ture, such as melancholia or spontaneously occurring panic attacks, would suggest a role for biological disturbances in combat veteran patients that overlap other clinical populations.

Temporal sequence of illness onset is also an important factor in defining relationships between primary and secondary illnesses. Course of illness has received much attention in other anxiety and affective disorders and has suggested mechanisms for illness progression (10-12). To our knowledge, the only study in the literature that has addressed sequence of illness onset in a veteran population with PTSD is that of Davidson et al. (5).

To obtain information on psychiatric conditions associated with combat-related PTSD, we recruited a clinical sample of veterans of high war zone stress from different military eras, including a group of former prisoners of war. In order to reduce potential confounds, we excluded patients with recent substance use disorders or severity requiring inpatient psychiatric treatment. In this report we provide information on the phenomenology and course of PTSD comorbidity in order to address the questions of whether comorbid symptoms appear specific to PTSD and trauma and whether there is a characteristic course for their emergence.

METHOD

Subjects

The majority of the patients were recruited from subjects consecutively referred to a newly established mental hygiene clinic PTSD program, primarily from Veterans Administration Medical Center clinical services. Additional subjects were established patients referred by other mental hygiene clinic clinicians who were familiar with the study's objectives and inclusion criteria. Patients were included if they had been in direct combat or high stress combat support roles, such as helicopter or field medic assignments, for a minimum of 3 consecutive months and/or had been prisoners of war. All of the included patients had also been repeatedly exposed to life-threatening situations and casualties. Patients were excluded if they had diagnoses of psychosis or dementia or had any other clinical signs of unreliable reporting. Patients were also excluded if they met criteria for alcohol or substance use disorder or had had a psychiatric inpatient admission within the past 2 years.

Procedure

Evaluations for screening and initial data gathering were conducted by a psychiatric social worker (C.A.R.). These assessments were semistructured and covered military histories, postmilitary social and occupational functioning, and family, social, and psychiatric histories. Information on experiences during combat and captivity was first elicited by open-ended inquiry, followed by establishment of the presence or absence of

specific stressors, including items on the Combat Exposure Scale of Lund et al. (13). Veterans Administration medical center records and military discharge forms were reviewed to verify service in a combat zone or captivity.

Psychiatric evaluation followed the initial assessment. After further review of military and family psychiatric histories, lifetime psychiatric diagnoses were determined by structured diagnostic interviews. These interviews used the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (14) to evaluate for Research Diagnostic Criteria and DSM-III-R anxiety, affective, and substance use disorders and to rule out psychotic disorders. Items were added to further address specific phenomenology and DSM-III-R hierarchical distinctions, which were conservatively applied. For example, the diagnosis of generalized anxiety disorder required a focus of worry other than war-related themes. The diagnosis of panic disorder was designated only if panic attacks occurred that were not provoked by specific stimuli, including reminders of combat, loud noises, interpersonal confrontations, or phobic situations. Phobic disorders were diagnosed for fear and avoidance of situations typical of phobias (e.g., crowded places, traveling distances, closed-in spaces, social scrutiny). The diagnosis of phobia also required that typical responses to the situations featured discomfort and/or anxiety and not the reexperiencing of trauma or fear of external threat. Since the SADS-L does not specifically evaluate PTSD criteria, a section from the Structured Clinical Interview for DSM-III-R, previously used to investigate PTSD (1), was added. If full or partial criteria for a disorder were established, patients were queried as to when the specific symptoms began. Additional questions addressed the subsequent course and severity of the disorder in question.

Psychiatric assessment also served to further evaluate for excluded conditions. In addition to diagnostic interviewing, patients were scrutinized for signs of pathological alcohol or drug use. Adequate recall ability in the World War II era veterans was confirmed by formal testing of address item recall and knowledge of major historical events and dates. Information from clinical records and the consistency of reporting within evaluations and clinical contacts were also considered. Patients were seen by the study team a minimum of three visits, and most were followed for subsequent treatment. Psychiatric evaluations were either conducted directly or supervised, with face-to-face follow-up interview, by the primary investigator (T.A.M.).

Data Analysis

Patients were grouped as those who had served in combat in Vietnam (Vietnam combat veterans) (N=27), those who had served in combat in World War II or Korea (non-Vietnam combat veterans) (N=18), and former prisoners of war (N=15) who also had served in World War II or Korea. Demographic and military history variables were compared between the groups; cate-

gorical variables were analyzed by chi-square analysis and continuous variables by analysis of variance. The number of patients who met lifetime criteria for a disorder were also compared between the study groups by chi-square analysis. The mean age at onset of the disorders found in sufficient numbers of subjects was compared to PTSD (which was the most prevalent disorder and, on average, the disorder of earliest onset) by paired t tests (two-tailed).

Characteristics of the Study Sample

Demographics. The average ages of the three groups were as follows: Vietnam combat veterans, 42.9 years (SD=3.6, range=38–57); non-Vietnam combat veterans, 67.4 years (SD=4.3, range=59–77); and former prisoners of war, 65.9 years (SD=4.5, range=58–71) ($F=123$, $df=2$, 59 , $p<0.001$). The Vietnam combat veterans group was more ethnically heterogeneous than the other two groups. Nineteen percent (N=5) were black and 37% (N=10) were Hispanic. The remaining Vietnam combat veterans (44%, N=12) and all but one Hispanic non-Vietnam combat veteran (6%) and one black former prisoner of war (7%) were white (Vietnam combat veterans versus non-Vietnam combat veterans versus prisoners of war: $\chi^2=18.5$, $df=4$, $p<0.001$).

Military stressors. Ninety-six percent of the 27 Vietnam veterans were assigned to Army (N=20) or Marine (N=6) infantry units where stressors included exposure to death and dismemberment of U.S. soldiers, fire from the enemy, sleep deprivation, and, in many, exposure to or responsibility for civilian casualties (81%). Sixty-seven percent of the non-Vietnam veterans (N=12, all Army) and 60% of the former prisoners of war (eight Army veterans and one Marine veteran) had also served in infantry units and endorsed a similar profile of combat stressors. Exposure to civilian casualties was somewhat less characteristic (50%) and possibly less extreme for the non-Vietnam combat veterans and former prisoners of war. Non-Vietnam combat veterans also included veterans of Navy combat in the Pacific theater (28%, N=5), and former prisoners of war included Air Force veteran flight combatants (33%, N=5). Statistical comparison of branch of service revealed Air Force ($\chi^2=12.5$, $df=2$, $p<0.05$) and Navy ($\chi^2=19.3$, $df=2$, $p<0.001$) service, but not Army ($\chi^2=0.9$, $df=2$, n.s.) and Marine ($\chi^2=5.7$, $df=2$, n.s.) service, to be differentially represented across the study groups.

In addition to combat stressors, former prisoners of war were often exposed to threats, physical abuse, deprivation of food and nutrition, and cold during captivity. The mean duration of captivity was 18.2 months (SD=7.1, range=7–33) and typically exceeded the duration of combat exposure before captivity. Thirty-three percent of the Vietnam combat veterans (N=9) and former prisoners of war (N=5) and 55% (N=10) of the non-Vietnam combat veterans had been wounded during combat ($\chi^2=1.96$, $df=2$, n.s.). Combat Exposure Scale scores were also comparable across the three groups (mean=4.9, SD=1.0 for Vietnam combat veter-

ans; mean=4.6, SD=1.0 for non-Vietnam combat veterans; mean=4.9, SD=1.1 for former prisoners of war) ($F=0.57$, $df=2$, 59, n.s.).

Psychosocial histories. On average, the patients had completed high school and some college. The Vietnam combat veterans tended to have had somewhat more education (Vietnam combat veterans: mean=14.0 years of school, SD=1.9; non-Vietnam combat veterans: mean=12.7 years, SD=2.1; prisoners of war: mean=12.5, SD=1.6) ($F=10.4$, $df=2$, 59, $p<0.001$). The majority of patients in all three groups were married at the time of evaluation (70%, $N=19$ of the Vietnam combat veterans; 67%, $N=12$ of the 18 non-Vietnam combat veterans; 73%, $N=11$ of the prisoners of war) ($\chi^2=0.18$, $df=2$, n.s.). During the past 10 years or 10 years before retirement age, the Vietnam combat veterans had been employed a mean of 75.9% (SD=33.2%) of the time, non-Vietnam combat veterans 67.4% (SD=4.3%), and former prisoners of war 82.9% (SD=28.9%) ($F=0.08$, $df=2$, 59, n.s.). Only one of the study patients, who had served in Vietnam, had a history of legal problems, and all were discharged from the military under honorable conditions.

Twenty-two percent of the total sample ($N=13$) reported histories strongly suggestive of psychiatric illness in immediate family members (seven Vietnam combat veterans, four non-Vietnam combat veterans, and two prisoners of war) ($\chi^2=1.4$, $df=2$, n.s.). An overlapping 30% ($N=18$) reported significant trauma before age 12, such as losing a parent through death or separation or having been abused or neglected (11 Vietnam combat veterans, four non-Vietnam combat veterans, and three prisoners of war) ($\chi^2=2.81$, $df=2$, n.s.).

Fifty-two percent ($N=31$) of the patients had received psychiatric treatment before contact with the study team. Treatment typically involved pharmacotherapy and supportive psychotherapy (received by 19 Vietnam combat veterans, seven non-Vietnam combat veterans, and five prisoners of war) ($\chi^2=0.24$, $df=2$, n.s.). Twenty-two percent of Vietnam ($N=6$) and non-Vietnam ($N=4$) combat veterans and none of the former prisoners of war had previous (remote) psychiatric hospitalizations ($\chi^2=0.68$, $df=2$, n.s.).

RESULTS

Prevalence of Disorders

The mean number of lifetime disorders per patient was 3.1 (SD=1.7, range=0 to 6). PTSD was the most prevalent lifetime disorder in the sample, with 82% ($N=49$) having met full criteria (table 1). The remaining 18% ($N=11$) of the patients reported symptoms that met criteria for one or two of the three diagnostic clusters for PTSD (see table 1, features column). Sixty-eight percent ($N=41$) of the sample also met full lifetime criteria for *DSM-III-R* major depression, 55% ($N=33$) for panic disorder, 53% ($N=32$) for generalized anxiety disorder, and 33% ($N=20$) for phobia. Subsyndromal

symptoms (i.e., those that did not meet full severity or duration criteria) were found for phobic disorders in an additional 27% of the sample, for obsessive-compulsive disorders in 20%, and for manic episode (hypomania) in 15%. Past histories that met criteria for alcohol or substance use dependence were elicited in 32% ($N=19$) of the patients. Each disorder was similarly represented in the three study groups (by chi-square comparisons) except for panic disorder. Two-way comparisons confirmed that panic disorder was underrepresented in the former prisoners of war ($N=17$, 63% of Vietnam combat veterans; $N=13$, 72% of non-Vietnam combat veterans; $N=3$, 20% of prisoners of war) (Vietnam combat veterans versus prisoners of war: $\chi^2=13.6$, $df=1$, $p<0.01$; non-Vietnam combat veterans versus prisoners of war: $\chi^2=9.2$, $df=1$, $p<0.01$; Vietnam combat veterans versus non-Vietnam combat veterans: n.s.).

Features

Of the 11 patients who had "partial" PTSD, nine met the criteria for the disorder except for *DSM-III-R* cluster C (symptoms of numbing and withdrawal). The remaining two patients with partial PTSD were both former prisoners of war and reported symptoms that met criteria *only* for numbing and withdrawal.

Criteria for melancholic type were present in 34% ($N=14$) of the 41 patients with major depression for a minimum of 2 consecutive weeks during the course of the condition. Patients who met full or subthreshold diagnostic criteria for panic disorder by definition experienced attacks that were unprovoked in nature. Seventy-one percent ($N=27$ of 38) of these patients' panic attacks included episodes that were reported to awaken them from sleep without dream recall. In 78% ($N=28$) of the 36 patients with phobic symptoms, the predominant phobic situations included crowded places. Other common phobic situations were social (being a focus of attention: 31%, $N=11$), traveling distances (19%, $N=7$), and closed-in spaces (three former prisoners of war, 8%). One veteran, who had been in a helicopter crash, developed a marked fear and avoidance of elevators. The predominant obsessive-compulsive symptoms were excessive checking behaviors in 71% ($N=10$) and ego-alien aggressive thoughts in 29% ($N=4$) of the 14 affected patients.

Onset

In all but one of the patients the original onset of PTSD symptoms was acute by the *DSM-III-R* definition (within 6 months of the stressful experience). One patient reported a history of childhood separation anxiety, and another reported the onsets of generalized anxiety disorder and major depression in late childhood and alcohol abuse in adolescence. Otherwise, the onsets of disorders were reported to have been proximate to, or sometime after, combat exposure.

The comparisons of mean age at illness onset include the comorbid conditions adequately represented and

TABLE 1. Lifetime Prevalence of PTSD and Related Psychiatric Disorders in Combat Veterans

DSM-III-R Diagnosis	Total (N=60)				Vietnam Veterans (N=27)				World War II and Korean War Veterans							
			Met Sub-threshold Criteria				Met Sub-threshold Criteria		Non-POWs (N=18)				POWs (N=15)

cases in which at least an approximate time of symptom onset was recalled. Onset of panic disorder (mean=31.3 years; $t=4.5$, $df=37$, $p<0.001$), major or minor depression (mean=30.0; $t=4.2$, $df=46$, $p<0.001$), and phobia or phobic symptoms (mean=27.6; $t=2.9$, $df=35$, $p<0.01$) was later than onset of PTSD (mean=23.2) (table 1), in contrast to generalized anxiety (mean=24.3 years; $t=0.94$, $df=33$, n.s.) and alcohol/substance use disorders (mean=25.4; $t=1.4$, $df=18$, n.s.). Similar relationships of onsets of illnesses were found for comparisons made within the study subgroups.

Subsequent Course

DSM-III-R PTSD symptoms per se, particularly those involving the reexperiencing of trauma, were reported to have significantly diminished in frequency and intensity from the first year or several years after combat or captivity in 45% (N=27) of the total study sample. In the remaining 55% (N=33), PTSD symptoms had been persistent or recurrent. Depression and generalized anxiety disorders were even more frequently described as persistent or recurrent; only 19.5% (N=8) of the patients with major depression and 6.0% (N=2) of the patients with generalized anxiety disorder reported discrete, time-limited episodes. The frequency of panic attacks varied episodically. While phobias and obsessive-compulsive symptoms were typically not severe, they were persistent in virtually all of the affected patients. Among the patients who met criteria for past alcohol or substance abuse or dependence, pathological use of alcohol or substances was reported to have been absent for a mean 12.1 years (SD=11.4, range=3-40). Several of these patients reported that discontinuation was associated with exacerbations of other symptoms.

DISCUSSION

The study sample in the present study consisted of symptomatic veterans whose lifetime psychiatric morbidity was initially provoked or significantly affected by severe, war-related stress. Consistent with previous studies (1-7), we found a high frequency of typically persistent anxiety and affective symptoms in association with PTSD in our study subjects. Our findings further suggest that these psychiatric conditions phenomenologically overlap other clinical populations; however, the pattern of occurrence of some specific symptoms also suggests a relationship to trauma. In addition, the ubiquitous presence of lifetime symptoms of PTSD and certain observations on course of illness are consistent with the hypothesis that PTSD represents a primary pathogenic process.

We found, similarly to a study of victims of civilian disasters (15), that among PTSD symptoms, numbing and withdrawal occur more variably than reexperiencing and heightened arousal. Persistent numbing and withdrawal in two former prisoners of war, who had little other psychiatric morbidity, suggests that restricting emotions and avoidance behavior may be partially adaptive for some patients. Panic and major depression were, on average, the disorders most delayed in onset compared to PTSD and also emerged somewhat later than the median age at onset (23 years) for both disorders in men that was reported in the Epidemiologic Catchment Area study (16). These observations on course of illness suggest that panic and depression, as they occur with PTSD, can represent secondary complications and manifestations of illness progression. Conversely, the relatively early emergence of generalized anxiety disorder suggests that symptoms of the disorder

TABLE 1 (continued)

Age at Onset (years)			Features
Mean	SD	Range	
23.2	4.0	18-37	Nine (15%) met <i>DSM-III-R</i> criteria A, B, and D only; two (3%) met criteria A and C only
30.0	12.3	12-69	Fourteen (30%) had lifetime melancholia
31.3	12.0	19-67	Twenty-seven (70%) had panic attacks during sleep
24.3	6.0	12-43	
27.6	10.3	7-61	Twenty-eight (78%) had phobia of crowded places, 11 (31%) of social situations, seven (19%) of traveling distances, and three (8%) of closed-in spaces
25.4	7.3	15-44	
24.3	5.3	16-34	Ten (71%) experienced excessive checking, four (29%) aggressive thoughts
26.5	6.0	20-35	Hypomania

der, like PTSD, may represent a primary response to trauma.

Our findings are limited by their retrospective nature. One recall bias could be a tendency to link symptom onset to dramatic life events. This would not account for finding certain conditions to be delayed in onset relative to PTSD, however. We further believe that the exclusion of patients with recent pathological substance use and the focus on a relatively functional outpatient sample enhanced the reliability of reported information. In addition, the comparable degree of psychosocial risk factors and military stress, excluding captivity, and comparable comorbidity profiles between our study groups support the validity and some generalizability of these findings. The sequence of onset of psychiatric conditions in our study is quite similar to the findings of Davidson et al. (5). The relative prevalence of disorders in our sample is also similar to the aforementioned study, which also recruited outpatient veterans of Vietnam and World War II combat (5). We also found a lifetime prevalence of PTSD in the prisoners of war which was similar to that reported in a recent study of former prisoners of war recruited through outreach sources (67% versus 50%) (17). The prevalence of major depression and panic disorder in the Vietnam veteran subgroup, however, exceeds the rates of co-occurrence with PTSD documented in a community-based sample of Vietnam veterans in the National Vietnam Veterans Readjustment Study (78% versus 26% and 63% versus 8%, respectively). The corresponding rates for generalized anxiety disorder were more comparable (56% versus 44%). Thus, our findings appear to be representative of a relatively symptomatic and chronic, albeit functional, subgroup of veterans with psychiatric morbidity related to war trauma.

Symptom patterns that are considered markers of endogenous disturbances (e.g., "spontaneous" panic attacks, major depression, melancholic features) were common in our sample. In fact, the percent of the PTSD patients with comorbid panic who reported attacks during sleep (70%) is almost identical to the prevalence of panic attacks during sleep in a panic disorder population (69%) (18). One explanation for these observations is that factors which predispose individuals to affective and other anxiety disorders may have a role in influencing susceptibility to PTSD. An alternative but not mutually exclusive possibility that is consistent with epidemiologic data (7) is that trauma and PTSD influence the concurrent or delayed emergence of other psychiatric disturbances. Progression of illness from symptoms specific to PTSD, in which anxiety is evoked by trauma-related or startling stimuli, to phobic situations, to spontaneous panic attacks suggests a process in which symptomatic responses occur increasingly autonomously. Such a process is consistent with the model of electrophysiologic kindling, which has been postulated to be involved in PTSD (19) as well as in affective illness (10) and in panic attacks associated with cocaine use (9). It is also possible that evolving disturbances in neurotransmitter functioning may underlie PTSD and the emergence of co-occurring conditions. Some studies have suggested increased noradrenergic activity in PTSD (20, 21). Chronic overactivity might effect secondary and tertiary changes of neurotransmitter depletion and sensitization of receptor subsystems. Such dysregulation of the noradrenergic system has been invoked in depression and panic disorder (22, 23). It has also been suggested that hypertension is a potential consequence of heightened noradrenergic activity related to sympathetic arousal in populations with PTSD (24). It is therefore of interest that we have recently found that 53% of an overlapping PTSD group (70% in non-Vietnam era, 32% in Vietnam era patients) met criteria for hypertension, compared to 31% of a VA psychiatric comparison group of similar age and cardiovascular risk profile (O. Brawman-Mintzer, N. Hernandez, T. Mellman, unpublished observations).

The implication that mechanisms underlying PTSD comorbidity overlap other psychiatric disorders requires validation from studies of biological markers and treatment response. The possibility that disturbances which are thought to be genetically influenced might also be acquired through extreme stressors and subsequent responses to stress is, however, intriguing. The observations of specific symptom patterns that overlap other clinical populations but are also consistent with traumatic influence support such a hypothesis. For example, the relative predominance of the phobic symptom of fear of crowded places suggests a conditioning effect of combat, as do other associations of phobias with specific experiences (e.g., claustrophobia in three former prisoners of war, an elevator phobia in a helicopter crash survivor). Obsessive-compulsive disorder features of excessive checking behaviors and ego-alien aggressive thoughts also appear to be themati-

cally related to combat experiences. The finding that panic was relatively underrepresented in the former prisoners of war group may mirror the finding of Green et al. (25), who reported a positive association between panic disorder and past special combat assignments in Vietnam. Panic disorder is characterized by anxiety attacks that at times occur unpredictably. It is likely that special combat assignments featured unpredictable patterns of stress more typically than did captivity during World War II.

The association of other psychiatric disorders with PTSD is an important consideration in accounting for the chronicity that has been found in PTSD populations and in conceptualizing treatment strategies. From a more general perspective, it would appear that patterns of response to trauma have implications for a range of psychiatric phenomena.

Recovery and Relapse From Major Depressive Disorder in the Elderly

Gregory A. Hinrichsen, Ph.D.

Objective: Results from the National Institute of Mental Health (NIMH) Collaborative Study of the Psychobiology of Depression raised serious concerns about the longer-term prognosis for major depressive disorder in younger persons. However, little research has examined the prognosis for major depressive disorder in the elderly despite suggestions that they have poorer clinical outcomes than younger adults. The objective of this study was to 1) document rates of recovery and relapse from major depressive disorder in a large group of inpatient elderly and 2) compare recovery and relapse rates from major depressive disorder in the elderly with those in a mixed-age patient group from the NIMH collaborative study. **Method:** The psychiatric status of 127 elderly inpatients diagnosed with major depressive disorder by Research Diagnostic Criteria was evaluated for 1 year. The same diagnostic and follow-up methods to assess psychiatric symptoms employed in the NIMH study were used. **Results:** One year after study admission, 72% of elderly patients had recovered. Nineteen percent of recovered patients, however, had a subsequent episode of major depressive disorder. Recovery and relapse rates in the elderly did not significantly differ from those reported for the mixed-age group in the NIMH study. **Conclusions:** It is erroneous to single out the elderly as being more likely to have poorer longitudinal treatment outcomes than others. Study findings indicate the need for continued refinement of somatic and nonsomatic treatments for the elderly to improve rates of sustained recovery from depression.

(Am J Psychiatry 1992; 149:1575-1579)

In the last decade results from a series of studies sponsored by the National Institute of Mental Health (NIMH) raised serious concerns about the longer-term efficacy of established treatments for depression. Using multicenter data from the NIMH Collaborative Study of the Psychobiology of Depression (1), Keller and Shapiro (2) indicated that prognosis for major depressive disorder in a mixed-age population treated in an uncontrolled (naturalistic) fashion was modest. While three-quarters of the patients recovered within 1 year, over one-third of those who recovered subsequently relapsed. The mean age of the patients was 35.5 years, however, and it is unclear whether comparable rates of recovery from and relapse into major depressive disorder would be found in a group of elderly subjects.

While findings from the NIMH collaborative study alerted many to possible limitations of existing treatments, those delivering mental health services to the elderly have had long-standing concerns about the longitudinal efficacy of treatments for depression in this group. Early research (3, 4) suggested that the prognosis was poor for the depressed elderly, and some clinicians held modest treatment expectations for older patients. Findings from the NIMH study of depression suggested the possibility that poor longitudinal treatment outcomes may not be confined to the elderly but may reflect larger problems in how to optimize the treatment of depression. Nonetheless, age may be related to different treatment outcomes. An answer to this question, however, requires a direct comparison of longitudinal outcomes, using the same methodology, between older and younger patients.

Two longitudinal, naturalistic follow-up studies of depressed elderly subjects appeared after initial findings from the NIMH collaborative study were reported. They drew two different conclusions about the course of major depressive disorder in older patients. The view that the prognosis for depression in the elderly is poor was supported by Murphy (5), who found that only one-third of older depressed patients had a good outcome after 1 year of psychiatric treatment. In contrast, Baldwin and Jolley (6) reported that almost

Presented at the 144th annual meeting of the American Psychiatric Association, New Orleans, May 11-16, 1991. Received Sept. 19, 1991; revision received Feb. 12, 1992; accepted March 5, 1992. three-fifths of a group of depressed elderly they studied were well 1 year after hospital admission. Methodological differences between the two studies may have explained the variance in outcomes. Unfortunately, comparison of results from these two studies with those from the NIMH collaborative study was difficult, since they used different diagnostic and follow-up procedures. The question of whether the prognosis for depression differs in the elderly and in younger age groups thus remains to be addressed despite recent calls for research on this topic (7).

The present research longitudinally studied for 1 year a group of elderly patients who were psychiatrically hospitalized with major depressive disorder. The same diagnostic and follow-up methods to assess psychiatric symptoms employed in the NIMH collaborative study of depression were used. The goals of this report are to 1) document rates of recovery and relapse among a group of inpatient elderly with major depressive disorder and 2) compare recovery and relapse rates in the elderly with those found in a mixed-age group of patients from the NIMH study.

METHOD

Sample

Baseline. Persons 60 years or older, admitted to the psychiatric inpatient service of a hospital, who met Research Diagnostic Criteria (RDC) (8) for major depressive disorder, participated in the study. Patients were not included if they had a documented history of bipolar disorder, schizophrenia, or neurological deficits or evidenced an organic brain syndrome or disorder. Since the research was part of a larger study of family issues in late-life depression (9), patients eligible for the study were required to have an involved spouse or adult child. Patients were interviewed with the Schedule for Affective Disorders and Schizophrenia (SADS) (10). A total of 150 patients agreed to take part in the research; they represented 84% of those who were eligible for the study. Informed consent was obtained from participants after study procedures were explained. During psychiatric hospitalization, which lasted a mean of 6.5 weeks ($SD=3.6$), elderly patients were treated in an uncontrolled fashion with antidepressant medications and/or ECT.

Follow-up. At 6 months and 1 year after hospital admission, older patients and their respective family members were interviewed by using the psychiatric status ratings from the Longitudinal Interval Follow-Up Evaluation (11) and other indices that characterized their psychiatric condition. Among the original group of 150 patients, data on longitudinal psychiatric status were successfully gathered on 127 patients (85%). Of patients for whom follow-up data were not obtained (and who were therefore not included in these analyses), five (3%) had died, 16 (11%) refused interviews, and two (1%) could not be reached. There were no sig-

nificant demographic or clinical differences between those who remained in the study and those from whom we were unable to collect follow-up data.

Study Measures

Baseline. Demographic information gathered on patients included sex, marital status, age, race, religion, and socioeconomic status, measured by the Four Factor Index of Social Status (12). Descriptors of the patient's past and current psychiatric history were derived from the SADS. The interviews for the SADS and Longitudinal Interval Follow-Up Evaluation (discussed later) were conducted by one research staff member with extensive training in the administration of these instruments. All study diagnoses and Longitudinal Interval Follow-Up Evaluation ratings were reviewed by the author. These included age at onset of major depressive disorder; history of prior episodes of major depressive disorder; duration of index episode of major depressive disorder; whether the index episode was superimposed on a chronic depression ("double depression") (13); severity of depression, rated with an equivalent of the Hamilton Rating Scale for Depression (14); and whether the index episode had psychotic features. A staff rating of the patient's physical health status was also obtained.

Follow-up. Follow-up assessments were made by using the psychiatric status ratings from the Longitudinal Interval Follow-Up Evaluation. The psychiatric status ratings were used to evaluate the prior 6 months of the patient's psychiatric condition. The course of psychopathology was then recorded by using a rating system linked to the RDC. On the basis of explicit Longitudinal Interval Follow-Up Evaluation criteria, recovery was defined as 8 continuous weeks in which the patient evidenced no or minimal symptoms of depression. Patients were classified as relapsed if they had recovered from the index episode of major depressive disorder and subsequently met the RDC for another episode of major depressive disorder during the 1 year period after admission to the study. A complete description of the Longitudinal Interval Follow-Up Evaluation methodology has been detailed elsewhere (11). During each 6-month follow-up assessment, the following information was also obtained: 1) scores on the SADS-derived measures of functional impairment secondary to the patient's psychiatric condition; 2) scores on the SADS Global Assessment Scale; 3) Global Improvement Scale scores; 4) emergence of suicidal behavior; and 5) the patient's characteristic treatment status.

RESULTS

About two-thirds of the patients in this study were married and widowed women. The vast majority (97%) were white. As can be seen in table 1, most patients were Jewish or Catholic, occupied middle levels of social status, and had an average age of 71 years.

TABLE 1. Demographic and Clinical Characteristics of 127 Elderly Depressed Patients

^aThe mean age of the patients was 70.9 (SD=6.8), and the mean equivalent Hamilton depression score was 24.5 (SD=5.7).

^bData not available for all subjects.

Almost three-quarters of the patients had an onset of major depressive disorder after age 50, and a similar proportion had had prior episodes of major depressive disorder. As reflected in the mean Hamilton equivalent score of 24.5, patients were severely depressed at admission, with episodes that had lasted a median of almost 4 months. One-fifth had psychotic depressions, and 9% had an index episode that was superimposed on a chronic depression. The majority of older patients were in fair to excellent physical health.

Recovery and Relapse at 1 Year

Clinical outcomes for this study (and those from the NIMH collaborative study) are summarized in tables 2 and 3. Table 2 reports the proportion of patients who recovered and relapsed over 1 year from study admission. Table 3 provides a general characterization of the patients' psychiatric condition over 1 year, including information about the presence of concurrent psychiatric symptoms among patients classified as recovered. Summarizing data in these two ways facilitated comparison

^aRelapse rates calculated only on those subjects who recovered. Data not available for one subject in the present study.

^bFor the present study, diagnoses included major depressive disorder (N=17) and RDC-defined minor depressive disorder (N=4); for the NIMH study, diagnoses included major depressive disorder (N=16), minor depressive disorder (N=7), mania (N=2), and hypomania (N=2).

of this study's findings with those derived from the NIMH study.

As can be seen in table 2, 72% of study participants recovered from the index episode of major depressive disorder by 1 year from date of hospital admission. Nineteen percent of those who recovered subsequently developed an additional episode of major depressive disorder within 1 year from admission. A higher proportion (23%) relapsed into any diagnosable affective episode (i.e., major depressive disorder or minor depressive disorder). The general characterization of all study participants over the course of 1 year (summarized in table 3) indicates that 59% recovered from the index episode of major depressive disorder and did not relapse into another episode, 13% recovered but later relapsed into major depressive disorder, and 28% did not recover during the year study period. It is noteworthy that 31 (42%) of the 74 patients classified as having fully or partially sustained recovery nonetheless experienced nondiagnosable affective symptoms or minor depressive disorder in the period after recovery from the index episode.

Other findings from this research (not presented in tables) indicated that at 1 year after entry into the study, 63.5% of study patients were judged much or very much improved, 36% still had at least some functional impairment due to psychiatric illness, and 8.7% had made (unsuccessful) suicide gestures or attempts and that Global Assessment Scale scores improved from an index episode average of 38.0 (SD=8.4) to 69.3 (SD=15.4). Further, the characteristic treatment status of study patients in the year-long follow-up was as follows: 10.2% not in treatment, 86.7% in outpatient psychiatric treatment, and 3.1% psychiatrically hospitalized.

^bFour subjects with mania/hypomania are classified as recovered (i.e., no subsequent episode of major depressive disorder) to facilitate comparison of findings.

Comparison of Findings With the NIMH Collaborative Study of Depression

Comparison of this study's findings with NIMH collaborative study results reported by Keller and Shapiro (2) offers a particularly valuable opportunity, since both used the same diagnostic and psychiatric follow-up methods. The two studies differed, however, on several demographic and clinical descriptors. Patients in the present study were more likely to be currently married and female than were those in the study of Keller and Shapiro (2). All of the patients in the present study had a diagnosis of major depressive disorder and were hospitalized, whereas 25% of the patients described by Keller and Shapiro were outpatients and had bipolar disorder. In addition, the duration and severity of the index episode were less, and fewer patients had superimposed depression than those who participated in the collaborative study of depression. Number of prior episodes and proportion of patients with psychotic depression were comparable in the two study groups.

As seen in table 2, there were no significant differences between the two studies on recovery from the index episode of major depressive disorder ($\chi^2=0.01$, $df=1$, n.s.) or relapse into another major depressive disorder among those who recovered ($\chi^2=0.05$, $df=1$, n.s.). Of the two studies, a higher proportion of Keller and Shapiro's participants (2) developed diagnosable affective episodes (36% versus 23%); however, the difference was not statistically different ($\chi^2=2.74$, $df=1$, n.s.).

Findings in table 3 reveal no differences between the two studies in a general characterization of the psychiatric condition of patients as fully or partially recovered (present study: 59%, Keller and Shapiro: 58%), remitted with relapse into same condition as index episode (13% versus 16%), or not recovered (28% versus 26%) ($\chi^2=0.31$, $df=2$, n.s.). Similar to findings from the present study, in Keller and Shapiro's study 29 (53%) of 59 patients classified as having fully or partially sus-

tained recovery evidenced minor affective symptoms or diagnoses after recovery.

DISCUSSION

In this study 72% of elderly inpatients recovered from an episode of unipolar major depressive disorder within 1 year. However, 19% of those who recovered subsequently relapsed into another episode of major depressive disorder. Rates of recovery and relapse did not significantly differ from those found in a mixed-age population of the NIMH collaborative study of depression (2) that used the same diagnostic and follow-up methodology.

While this research found that the majority (59%) of older adults did recover from an episode of major depressive disorder and did not relapse into another episode, over two-fifths of the recovered subjects subsequently experienced nondiagnosable affective symptoms or, less often, minor depressive disorder. Keller and colleagues (15) have suggested that one reason for the modest clinical psychiatric outcomes they found in a mixed-age population is that patients are not treated with sufficiently high doses of antidepressant medication. Our findings underscore, however, that it is erroneous to single out the elderly as being more likely to have poor treatment outcomes from major depressive disorder, since their recovery and relapse rates are comparable to those in a group of predominantly younger individuals.

There are two limitations of a comparison of this study's findings with those reported by Keller and Shapiro (2). The first is that the two study groups differed regarding several demographic and clinical characteristics. It is possible that these differences were related to recovery and relapse. Only one of the variables on which there was a significant difference between the two study groups, duration of episode, was in fact related to poorer outcome by Keller and Shapiro (2). A reexamination of data from this study, however, found no relationship between any of the demographic and clinical descriptors on which the two study groups differed and recovery or relapse in the elderly. Future comparisons between mixed-age and elderly patients will most likely also continue to find demographic and clinical differences between these two groups. Demographic descriptors change as a function of age (e.g., sex differences in life expectancy result in increasing proportions of women in later life), as do clinical descriptors (e.g., older persons have more years at risk for episodes of psychiatric illness than younger persons). One factor that was not systematically assessed in this research but should be in future studies is types of treatment received, since treatment differences may be related to clinical outcomes.

The second limitation is that only patients with involved spouses or adult children were included in the present study. If family involvement in care of a depressed individual were related only to better clinical outcomes, our findings might be portraying a more fa-

avorable response to treatment than would have been found in a sample that included never-married persons or ever-married individuals without family support. A large body of research on patients with schizophrenia and depression indicates, however, that family members can have both positive and negative effects on the course of psychiatric illness in their patient relatives (16).

It is difficult to directly compare this study's findings with those of Murphy (5) and with Baldwin and Jolley's widely cited follow-up studies of the depressed aged (6) because of their different diagnostic and follow-up procedures. A general comparison of their results with those of the present study and Keller and Shapiro's study (2) is nonetheless informative since Murphy (5) and Baldwin and Jolley (6) conducted 1-year, naturalistic, follow-up studies. If patients who died or developed dementia are excluded from Baldwin and Jolley's and Murphy's outcome data, 67 of 103 patients (65%) in Murphy's study and 72 of 90 patients (80%) in Baldwin and Jolley's study recovered from an index episode. These results do not significantly differ from those of the present study and those of Keller and Shapiro (2) ($\chi^2=5.53$, $df=3$, n.s.). In Baldwin and Jolley's study, 26 of 72 patients (36%) who recovered later relapsed into an episode of depression—a rate significantly higher than that in the present study and in Keller and Shapiro's ($\chi^2=7.25$, $df=2$, $p<0.05$). It was not possible to calculate a relapse rate from Murphy's published data that allowed comparison with the other studies, since her definition of "recovered" patients may have included those who relapsed but who again recovered by the end of 1 year. It therefore appears that with respect to recovery rates, there is convergence of outcomes among these four different studies.

In conclusion, these findings indicate that there is considerable similarity in treatment outcomes for elderly and younger patients treated in an uncontrolled fashion. Therapeutic pessimism based on age is unwarranted. Nonetheless, many patients in this study and in the NIMH collaborative study continued to evidence problems with depression in the year from study entry. These data indicate the need for continued development and refinement of somatic (17) and nonsomatic (18) treatments for the elderly that will increase the proportion of patients with sustained recovery from depression.

Prediction of Outcome in Mania by Mood-Congruent or Mood-Incongruent Psychotic Features

Mauricio Tohen, M.D., Dr.P.H., Ming T. Tsuang, M.D., Ph.D., D.Sc.,
and Daniel C. Goodwin, B.S.

Objective: The aim of this study was to determine the significance of mood congruence of psychotic features in mania as a predictor of outcome. **Method:** Fifty-four patients with bipolar disorder were followed prospectively for 4 years after recovery from an episode of mania with psychotic features. Assessments of residential and occupational status, interepisode symptoms, and episode recurrences were made at 6 and 48 months after recovery. Categorical outcomes were evaluated by logistic regression and recurrence risk with survival analysis. **Results:** Mood-incongruent psychotic features during the index manic episode predicted a shorter time in remission at 4 years (hazard ratio=2.6), and Schneiderian first-rank symptoms predicted poor residential status at 4 years (odds ratio=20.1). **Conclusions:** Differentiation of mood congruence of psychotic features in mania evidently has prognostic validity and, therefore, has utility as a nosological characteristic.

(Am J Psychiatry 1992; 149:1580-1584)

Presence or absence of psychotic features is a common basis for subdividing major affective syndromes. In *DSM-III-R* the fifth digit in the code number allows for the classification of manic episode with psychotic features and severe manic episode without psychotic features as well as the distinction of mood-congruent and mood-incongruent psychotic features. Traditionally, mood congruence has been associated with mood disorders and mood incongruence has been associated with schizophrenia, although *DSM-III* and *DSM-III-R* proposed that mood incongruence can occur in affective disorders. This tentative proposal requires validation.

Many investigators have tried to validate subtypes of affective disorders with follow-up studies. Specifically, the presence of psychotic features as a predictor of outcome in mania has been considered (1-10). Coryell et

al. (7) found that loosening of associations in a group of patients with psychotic and schizoaffective mania predicted a worse outcome at 5 years. Rosen et al. (6) found that patients with psychotic bipolar disorder showed poorer social functioning than patients with nonpsychotic bipolar disorder. Furthermore, Rosenthal et al. (5) found that patients with psychotic mania had longer periods of remission while receiving maintenance lithium treatment than did patients with nonpsychotic mania. Others (1-4, 8) have found no difference in outcome on the basis of the presence of psychotic features.

Several studies (11-18) have looked specifically at mood congruence of psychotic features in affective disorders in relation to outcome. Coryell and Tsuang (11) found that depressed patients with mood-incongruent features were younger and had a poorer outcome at 2-3 years but no difference at 40 years. Brockington et al. (16) found that manic patients with mood-incongruent psychotic features had a worse outcome than manic patients without psychotic features and manic patients with mood-congruent psychotic features. A recent report by Miklowitz et al. (17) indicated that "classical schizophrenic symptoms" have a prognostic utility in bipolar disorders. Abrams and Taylor (18), however, found no difference in outcome between patients with mood-congruent and mood-incongruent psychotic affective disorder. Kendler (19) recently published an empirical review of mood-incongruent psychotic affective illness. On the basis of a methodologically sound literature review, he concluded that mood-incongruent psychotic affective illness most likely represents a subtype

of affective disorder, as proposed in *DSM-III-R*, rather than a form of schizophrenia or a separate disorder.

Comparisons of such studies are complicated by variable definitions of "psychotic features." In their comprehensive book on manic-depressive illness, Goodwin and Jamison (20) summarized 26 studies of psychotic features in mania and reported that the prevalence ranged from 47% to 75% of patients with bipolar disorder at some time in the course of their illness and that the rate tended to decline with increasing age of onset. Black and Nasrallah (13) found psychotic features in 44% of 467 patients with bipolar disorder; 28% of the patients had mood-congruent psychotic features and 9% had mood-incongruent psychotic features. Kendler (19) called for more studies of mania that address the validity of mood congruence of psychotic symptoms.

We have previously reported that the presence of psychotic features in mania predicts poor outcome, including higher risk of relapse and poor psychosocial outcome (9, 10). We now report the significance of mood congruence of psychotic features as a predictor of outcome in mania.

METHOD

The present study involved a 4-year follow-up of 54 patients with bipolar disorder who, during their index episode, experienced mania with psychotic features. These 54 patients were drawn from a larger pool of subjects with psychotic and nonpsychotic mania in a study reported elsewhere (9). Most of the 54 patients in the current study were young, middle-class, and unmarried (table 1). Fifteen (27.8%) had had no previous episodes of mania. Their mean age was 30 years ($SD=9.5$). A *DSM-III* diagnosis of mania was obtained by using the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (22). All of the patients were at least 17 years of age, had recovered from the index manic episode at entry into the study, and provided informed consent. Recovery was defined operationally as reported elsewhere (9). Treatment was not under the control of the investigators.

At entry into the study, 30 (55.6%) of the patients had mood-incongruent features and 24 (44.4%) had mood-congruent psychotic features (table 1). We identified eight individuals with predominantly grandiose delusions but who also had persecutory delusions. We classified these patients as having mood-congruent psychotic features. In addition, we conducted a second analysis including them with the mood-incongruent group.

Psychotic features were defined according to *DSM-III-R* as the presence of either delusions or hallucinations or behavior so grossly disorganized that "a reasonable inference can be made that reality testing is markedly disturbed." Psychotic features were divided as to their mood congruence or incongruence according to *DSM-III-R* definitions and DIS data obtained by one

^aHollingshead criteria (21).

^bTwelve patients had both mood-congruent and mood-incongruent features; these patients were classified as having mood-congruent or mood-incongruent features depending on which type of feature predominated.

^cEight of the patients with paranoid delusions had predominantly mood-congruent delusions but also had nongrandiose paranoid delusions that were less prominent or milder.

of us (M.T.). Delusions and hallucinations were considered mood congruent when their content was consistent with a manic mood, such as "themes of inflated worth, power, knowledge, or identity or a special relationship to a deity or a famous person" (*DSM-III-R*). Psychotic features were considered mood incongruent if they did not involve such manic themes and included nongrandiose persecutory delusions, thought insertion, thought broadcasting, delusions of being controlled, or catatonic features. Patients who had both mood-congruent and mood-incongruent psychotic features ($N=12$) were assigned to the type that seemed to predominate.

Patients also were classified as having or lacking Schneiderian first-rank symptoms (23), which were considered mood-incongruent features according to the *DSM-III* definition. Mood-incongruent psychotic mania was differentiated from schizoaffective mania according to *DSM-III-R* definitions. For mania, the mood-incongruent features had to be restricted to periods of a full affective syndrome. In contrast, according to Research Diagnostic Criteria (24), the presence of certain psychotic features during a manic episode in an individual with good premorbid adjustment would qualify that individual for a diagnosis of a schizoaffective disorder.

To assess the reliability of the distinction between presence or absence of mood congruence and first-rank symptoms, an independent rater (D.C.G.) reviewed the medical records blind to the index assessment. Categorical correlations of the two raters were high (six disagreements out of a total of 54 assessments in both

cases). For mood congruence, kappa=0.78 (SD=0.09) (p<0.0001), and for first-rank symptoms, kappa=0.70 (SD=0.12) (p<0.0001).

Outcome Assessment

Patients were evaluated 6 and 48 months after discharge, as described elsewhere (9). Briefly, three outcomes were evaluated: 1) relapse (within the follow-up period), 2) interepisode symptoms, defined as psychiatric symptoms in the absence of a full *DSM-III* affective syndrome, and 3) residential status and occupational status. Residential status and occupational status were operationally defined by using the Modified Vocational Status Index (9) and the Modified Location Code Index (25).

Relapse was documented with the use of an abridged DIS (the sections on affective and psychotic disorders) (9). The use of the DIS also permitted us to assess the stability of the index diagnoses. To establish the reliability of the diagnosis obtained at the 4-year follow-up, an investigator blind to the diagnosis independently diagnosed patients with all available documentation. The kappa statistic for the agreement on diagnoses was 0.78 (SD=0.15) (p<0.001). There were two disagreements: in one case a patient was diagnosed as having bipolar disorder by one rater and schizoaffective disorder by the other and in the second case a patient was diagnosed as having schizoaffective disorder by one rater and schizophrenia by the other.

Interepisode symptoms were assessed by using the Brief Psychiatric Rating Scale (BPRS) (26) and the Bowditch Rating Scale (27); the latter rates hallucinations, delusions, affect, and speech on a scale of 0 (not present) to 10 (so severe as to interfere with meaningful function). The interrater reliability coefficient for

the Bowditch Rating Scale and the BPRS was 0.87 (p=0.001) (9).

Statistical Analysis

For categorical outcomes, adjusted odds ratios with 95% confidence intervals were obtained for the hypothesized risk factors, controlling simultaneously for the effects of age, gender, and history of previous episodes. A logistic regression model was fitted with the computerized Statistical Analysis System (SAS) (28).

To estimate relapse risk we analyzed survival curves by using Cox proportional hazard regression models with SAS assistance (28). Hazard ratios with 95% confidence intervals were obtained, again adjusting for age, gender, and presence of previous episodes.

RESULTS

Outcome information was obtained for all 54 subjects: three (5.6%) had committed suicide, 14 (25.9%) were interviewed face to face, and 37 (68.5%) were interviewed over the telephone. We reported elsewhere (9) the high reliability of the data collected by telephone.

At the 4-year evaluation, five (9.3%) of the 54 subjects had shifted diagnosis—four to schizoaffective disorder and one to schizophrenia. Twenty-seven (50%) were receiving antipsychotic drugs. The presence of mood-incongruent psychotic features during the index episode was associated with use of antipsychotic drugs at 4 years (adjusted odds ratio=5.9, confidence interval=1.5–24.2, p=0.01) after controlling for age, sex, and presence of previous episodes. No significant associations were found between type of psychotic feature during the index episode and sociodemographic variables, presence of previous episodes, or shift in diagnosis at 4 years.

Psychosocial Outcome

Logistic regression was used to predict psychosocial outcome at 4 years (table 2). Presence of first-rank symptoms and male gender predicted poor residential status after controlling for presence of mood-incongruent features, age, and presence of previous episodes (table 2). Presence of first-rank symptoms after controlling for the same variables almost reached statistical significance for the prediction of poor vocational status at 4 years (table 2). Mean age at index episode (30 years, SD=9.4) did not predict residential status (beta coefficient=-0.02, SE=0.04) or occupational status (beta coefficient=0.03, SE=0.04) at 4 years. No predictors were identified for poor outcome at the 6-month follow-up.

Relapse

Forty-one (75.9%) of the 54 patients suffered at least one episode of illness during the 4-year follow-up period.

In 17 (31.5%) of the 54 patients the first episode of relapse was depression and in 24 (44.4%) it was mania.

Mood-incongruent psychotic features predicted a shorter time in remission (hazard ratio=2.6, 95% confidence interval=1.2-5.5, $p=0.01$) after controlling for gender, age, and presence or absence of previous episodes. The median time in remission for patients with mood-incongruent psychotic mania was about 8 months, compared with 33 months for the patients with mood-congruent psychotic mania ($\chi^2=6.01$, $df=4$, $p=0.01$) (figure 1). When we classified the patients with predominantly grandiose and persecutory delusions as having mood-incongruent psychotic mania, we found no difference in risk of relapse between the mood-congruent and the mood-incongruent groups.

No predictors were identified for the presence of interepisode symptoms at 6 or 48 months.

DISCUSSION

It appears that the differentiation of mood-congruent and mood-incongruent psychotic features in mania has prognostic validity, adding support to this proposed distinction in *DSM-III-R*. Our findings indicate that presence of mood-incongruent psychotic features represents a risk factor for episode relapse in bipolar disorder, especially during the first year after recovery from an index episode of mania. Therefore, contrary to some previous reports (2, 3, 8, 29) but in agreement with others (5-7, 17, 19), the characteristics of psychotic symptoms during an index manic episode may have value in predicting the later course of bipolar illness. Mood incongruence also has been found to predict poorer outcome in major depression (11). The value of identifying first-rank symptoms in mania or depression has been questioned (29), and low reliability in its assessment has been suggested (30). However, we found good reliability in the identification of both first-rank symptoms and mood congruence. In our group of patients, presence of first-rank symptoms predicted poor psychosocial outcome at 4 years, suggesting the utility of their assessment in manic patients.

The identification of mood congruence as a predictor of outcome in mania may speak to a gradation of vulnerability in which mania without psychotic features has the best prognosis (9, 10), mania with mood-incongruent psychotic features has the worst prognosis, and mood-congruent psychotic features occupy a middle position regarding future risk. Thus, the present report supports a "severity continuum" hypothesis, as suggested by others (19, 31, 32). Furthermore, a recent 5-year follow-up study conducted by Coryell et al. (33) found that patients with schizoaffective mania had worse outcomes than patients with psychotic mania. Adhering to a continuum hypothesis, it would follow that schizoaffective mania would then be at the extreme of a severity scale. Furthermore, close to 10% of our study group had a change in diagnosis at the 4-year follow-up, which is similar to rates reported by other in-

FIGURE 1. Cumulative Probability of Remaining in Remission Over 48 Months for 54 Patients With Mood-Congruent and Mood-Incongruent Psychotic Mania

vestigators (34, 35). As recently discussed by Taylor (36), the boundaries of affective disorders, schizoaffective disorders, and schizophrenia need to be further investigated.

The identification of different courses and outcomes in a presumably single disorder represents an external validator of a nosological distinction (37). The present report suggests that manic episodes with mood-incongruent psychotic features may represent a severe presentation of bipolar disorder.

The issue of classifying psychotic mania as mood congruent or mood incongruent needs further clarification in the *DSM* system. Currently, there are no clear guidelines on how to classify an episode if both types of psychotic features are present. This differentiation is particularly relevant when grandiose and persecutory delusions are both present because they are the most common type of delusions experienced by manic patients (13). Our findings suggest that if both types of delusions are present and the episode is classified depending on which type is predominant, the two groups will differ in terms of risk to relapse. On the other hand, when we used the mere presence of persecutory delusions to classify our patients' episodes as mood incongruent there were no differences in outcome. Another option is to have a category defined as presence of both mood-congruent and mood-incongruent psychotic features. Only a few ($N=12$) of our subjects had both types of features, so we could not conduct further analysis of this possibility. The utility of such a category needs further validation.

Generalizations from the present findings should be made cautiously. These results may apply only to patients with bipolar disorder who recovered from an index manic episode that required hospitalization. Therefore, our subjects may represent less severely ill patients with bipolar disorder because they recovered from the index manic episode. On the other hand, a higher proportion of our patients than of other reported subjects

(13) had mood-incongruent features, which may suggest that our patients were more severely ill. In addition, due to the uncontrolled nature of treatment, no definite conclusions can be drawn as to the impact of treatment interventions on outcome or their interaction with mood-congruent or mood-incongruent psychotic features.

By identifying a significant association between the 4-year course of mania and mood congruence of psychotic features, the present report supports the validity of this nosological distinction, recently advocated by Kendler (19). It also highlights the importance of phenomenological and longitudinal assessment of patients with bipolar disorder. To further investigate the issue of stability of affective and psychotic disorders, prospective follow-up studies need to be conducted with diagnostic assessments at first episode and across longer periods of time. Finally, clinicians need to be aware of a possibly unfavorable outcome in manic patients with mood-incongruent psychotic features.

Psychotic Symptoms and Suicidal Behavior in Hospitalized Children

Richard Livingston, M.D., and H. Stefan Bracha, M.D.

Association of psychotic symptoms with suicidal behavior was studied in 90 hospitalized pre-pubertal children. Children with psychotic symptoms were more likely to have threatened or attempted suicide. The association of visual hallucinations with suicidal behavior was stronger than that of auditory hallucinations or psychotic ideation. The authors speculate that psychosis in general and visual hallucinations especially may be indicators of suicide risk among children.
(Am J Psychiatry 1992; 149:1585-1586)

Psychotic symptoms, including auditory, visual, and tactile hallucinations and delusional ideas, are commonly reported by children with major depression (1, 2). Depression is clearly established as a major risk factor for suicide in childhood, and there is evidence for a relationship of psychosis to severity of depression as well as to particular suicide-encouraging content in the hallucinations of depressed children (3). Shaffer et al. (4) observed a high rate of suicide among adolescents suffering from psychosis. Taken together, these findings suggest a need to look for associations of psychotic symptoms with suicidal behavior in younger children as well.

Suicidal behavior is a common reason for hospitalizing children in psychiatric units, so we used data from a hospital study group to test the following hypotheses: 1) children with psychotic symptoms are more likely to have engaged in suicidal behavior than children without psychotic symptoms, and 2) among psychotic symptoms, auditory hallucinations will be most highly correlated with suicidal behavior.

METHOD

One hundred children admitted consecutively to a children's psychiatric unit were given the Diagnostic In-

terview for Children and Adolescents, the methodology for which was described previously (5). The interview was administered by trained medical students and scored by the first author using *DSM-III-R* criteria. The suicide items of the Diagnostic Interview for Children and Adolescents and the recorded presence or absence of suicidal statements or attempts in the admission histories were used to determine suicidal behavior. Psychotic symptoms from the relevant section of the Diagnostic Interview for Children and Adolescents were scored as present or absent.

Of the 100 consecutively admitted children, five were discharged within 48 hours and therefore were not given the diagnostic interview, and five other children were excluded from the study because of incomplete or questionable responses in the interview. The 90 study subjects included 64 boys and 26 girls; 80% (N=72) were white and 20% (N=18) were black. Formal socioeconomic status ratings are not available, but 48 children (53.3%) were on public assistance. The children's ages ranged from 6 to 12 years (mean=9.9 years, SD=1.9). The mean IQ according to the WISC-R was 92 (SD=17).

RESULTS

Sixty-two children had more than one diagnosis according to the Diagnostic Interview for Children and Adolescents; the mean number of diagnoses for the group was 2.8 (SD=1.6). Seventeen children had major depression, and another 18 had more chronic depressive symptoms but did not fulfill the criteria for major

^aWith Yates's correction.

depression (they were clinically dysthymic, but the interview did not, until the more recent revision, explicitly address dysthymia). Thirty-nine children had only a behavior disorder (conduct disorder, oppositional defiant disorder, or attention deficit hyperactivity disorder). Other diagnosed emotional disorders, many in children who also had depression, included separation anxiety disorder (N=13) and overanxious disorder (N=16).

Seventeen children reported auditory hallucinations other than hearing their names called; all involved distinct voices either making derogatory comments or commanding them to harm themselves or others or engage in other forbidden acts. Six children, all boys, reported visual hallucinations, all of them of dead relatives. Twenty-four children acknowledged ideas of reference or persecution, and 15 reported thought broadcasting, thought insertion, mind reading, or other unusual thought experiences. In only eight cases were these judged to be delusional in proportion, and these eight children also had hallucinations. All of the children with hallucinations had one of the depressive diagnoses. Fifteen of the children who reported psychotic symptoms other than hallucinations reported at least some depressive symptoms.

Thirty-nine patients reported suicidal ideation. All of them had also made either suicidal statements/threats (N=22) or suicide attempts with or without threats (N=17). All 17 patients with major depression were in the group exhibiting suicidal behavior, as were 11 of the 18 with chronic depression.

The association of major depression with suicidal behavior was highly significant ($\chi^2=24.6$, df=1, $p<0.001$). Overall, children with depressive diagnoses were 16 times as likely to have threatened or attempted suicide as children without depressive disorder.

Five children who reported visual hallucinations of dead relatives had made multiple suicide attempts. Persecutory or referential ideas were reported by six who threatened suicide but only one who attempted suicide. Table 1 provides an overall comparison of psychotic symptoms in the suicidal (attempters and threateners) and nonsuicidal children interviewed.

The children who had attempted suicide differed in some respects from those who had threatened suicide. All of the attempters but only half of the threateners had a depressive disorder, and six of the threateners but only one attempter had persecutory or referential ideas.

DISCUSSION

Our first hypothesis is supported by these data: children with psychotic symptoms were three times as likely as nonpsychotic children to show suicidal behavior. The hypothesized specific risk associated with auditory hallucinations was not observed: children with visual hallucinations were more suicidal. Although the number is small, this finding is striking and deserves further exploration in relation to reunion fantasies, children's views of death, and the relation between grief and depression in youth.

Other findings that need further study include the possible association of persecutory ideas with suicide threats but not suicide attempts and the apparent lack of association of suicidal behavior with auditory hallucinations. Ideally, all of these associations will generate hypotheses for future study of both disturbed populations like ours and samples representative of broader populations, with some rating of suicidal behaviors as more and less serious both psychiatrically and medically.

Although the study of suicidal behavior among children and adolescents has recently accelerated, our current knowledge of risk factors for suicide among youngsters is extremely limited. We know that suicide threats and attempts are usually present in the histories of young people who commit suicide, and we know that depressive disorders are associated with suicidal statements and suicide attempts (3, 4). Our results indicate that in prepubertal children, psychotic symptoms in general and visual hallucinations of dead relatives in particular may increase the risk of suicidal behavior. We strongly recommend that these symptoms be inquired about as part of clinical assessment for suicide risk.

Amelioration of Mitral Valve Prolapse After Treatment for Panic Disorder

Jeremy D. Coplan, M.D., Laszlo A. Papp, M.D., Donald L. King, M.D.,
and Jack M. Gorman, M.D.

Twenty panic disorder patients with mitral valve prolapse showed amelioration of prolapse on repeat echocardiogram after treatment for panic disorder. This effect was significant when compared to repeat echocardiograms in eight psychiatrically normal control subjects with mitral valve prolapse.

(Am J Psychiatry 1992; 149:1587-1588)

The association of panic disorder and mitral valve prolapse is controversial. Studies have reported a greater than average prevalence of mitral valve prolapse in patients with panic disorder, although others have not confirmed this association (1, 2). Gorman et al. (1) reported that the majority of patients with panic disorder and mitral valve prolapse suffer from mild prolapse that is hemodynamically and clinically insignificant. This may be missed by overly stringent criteria and may account for discrepancies among studies.

Investigators have argued that mitral valve prolapse initiates panic disorder (3), that mitral valve prolapse and panic disorder are associated by mere chance (4), and that panic disorder causes mitral valve prolapse (5). In order to test the last hypothesis, we report on patients with panic disorder and mitral valve prolapse who underwent repeat echocardiograms after treatment for panic disorder.

METHOD

Subjects

Twenty subjects who met *DSM-III* criteria for panic disorder with or without agoraphobia and who showed

echocardiographic evidence of mitral valve prolapse were studied. The mean age of these subjects was 37.3 years ($SD=7.8$); there were five men and 15 women. Eight psychiatrically normal control subjects who showed incidental echocardiographic evidence of mitral valve prolapse were also included. Their mean age was 29.0 years ($SD=4.6$); there were two men and six women. Informed consent was obtained after the procedure was explained.

Procedure

All echocardiograms were performed by M-mode and two-dimensional techniques, with patients in the lateral decubitus position, and were read by the same cardiologist (D.L.K.). Mitral valve prolapse was diagnosed on two-dimensional imaging when posterior movement of either or both mitral valve leaflets relative to the annulus was observed during systole. On the M-mode tracing, mitral valve prolapse was manifested as an abrupt posterior change of direction of the mitral echo during systole; the normal echo usually inscribes a straight line. Severity of the prolapse was rated by M-mode as 1) no prolapse, 2) borderline prolapse: 2 mm or less, 3) mild prolapse: 3-4 mm, 4) moderate prolapse: 5-7 mm, and 4) severe prolapse: 8-10 mm.

Patients were then treated in an open fashion. Seven received only benzodiazepines, three received tricyclic antidepressants, and four received both. One patient received a tricyclic antidepressant, a benzodiazepine, and behavioral therapy, one a tricyclic antidepressant and lithium, and one a tricyclic antidepressant and behavioral therapy. One received a tricyclic antidepressant/monoamine oxidase inhibitor (MAOI) combination, and one received an MAOI with a benzodiazepine. Information on treatment and clinical status of one patient was not available. All patients showed some clinical improvement; 12 were evaluated as panic free and

seven as having a reduction of frequency and/or intensity of panic symptoms at the time of the second echocardiogram.

After a mean treatment period of 27.8 months ($SD=21.6$), the subjects underwent a repeat echocardiogram. Repeat echocardiograms were performed on the control subjects after a mean of 13.3 months ($SD=2.3$).

Data Analysis

The first analysis compared the ratio of patients who did not have evidence of mitral valve prolapse on repeat echocardiogram to those whose status did not change versus the same ratio in control subjects. We initially used a displacement cutoff point of 2 mm or greater to define mitral valve prolapse. We then repeated the analysis using a 3-mm cutoff, which has been viewed by cardiologists as the preferable standard for diagnosing prolapse (6). We also performed a Student's *t* test comparing the mean change in degree of prolapse from first to second echocardiogram between patients and control subjects. In a number of instances, the echocardiographer noted only the severity of prolapse on the report, not the millimeters of displacement. In those cases the following conversion was used: borderline—2 mm, mild—3.5 mm, moderate—6 mm, severe—9 mm.

RESULTS

The control group was younger than the patients ($t=2.8$, $df=26$, $p<0.005$). Baseline differences in degree of prolapse or sex differences between groups were not detected. The interval between echocardiograms was longer for patients than for control subjects ($t=1.9$, $df=26$, $p<0.04$). When the 2-mm cutoff point was used, 12 of 20 patients who originally had mitral valve prolapse were categorized as not having it. Of eight control subjects, two were categorized as not having mitral valve prolapse on repeat echocardiogram (from borderline to no mitral valve prolapse in both instances) (*n.s.*). When the analysis was repeated with the 3-mm cutoff point, nine of 15 patients were categorized as having no mitral valve prolapse after treatment for panic disorder, compared to none of six control subjects (Yates's $\chi^2=4.1$, $df=1$, $p<0.05$). Five patients and two control subjects with borderline prolapse on the first echocardiogram were excluded when the 3-mm cutoff was used. When the change in degree of prolapse between echocardiograms was compared, the patients showed a mean decrease in prolapse of 1.8 mm ($SD=1.8$), compared to a slight increase in prolapse in the control subjects (mean=0.1 mm, $SD=2.7$) ($t=2.2$, $df=26$, $p<0.02$).

DISCUSSION

The findings of this preliminary study suggest that mitral valve prolapse associated with panic disorder may be a consequence of the disorder itself. Although the analysis that used the 2-mm cutoff did not show a significant mitral valve prolapse conversion rate, when the more conservative 3-mm cutoff was used, the conversion rate became statistically significant. Further, the *t* test analysis, which did not use a specific cutoff point, showed an overall reduction in degree of prolapse in patients compared to control subjects. These findings should be qualified by certain methodological limitations, which include that the patient group were significantly older and had significantly longer intervals between echocardiograms than control subjects. Future replicative studies should carefully control for such factors, since they may have confounded the results of the present study.

The prolapse associated with panic disorder may result from autonomic overdrive, leading to temporary deformation in the mitral valve or desynchrony in ventricular contraction (7). Since patients received a number of treatments, including nonpharmacological ones, it is likely, but not yet proven, that the resolution of the prolapse was not due to a direct pharmacological effect but rather due to a general reduction in panic symptoms. A possible mechanism for amelioration of prolapse may result from an attenuation of autonomic overdrive, an effect of antipanic treatment (8).

Hyperventilation-Induced Cerebral Ischemia in Panic Disorder and Effect of Nimodipine

Daniel M. Gibbs, M.D., Ph.D.

Basilar artery blood flow was measured by transcranial Doppler ultrasonography before and during hyperventilation in nine patients with panic disorder and nine normal comparison subjects. The hyperventilation-induced decrease in basilar artery blood flow was significantly greater in patients with panic attacks than in comparison subjects. Two patients with decreases in basilar flow greater than 80% were successfully treated with nimodipine, a centrally active calcium channel blocker.

(Am J Psychiatry 1992; 149:1589-1591)

Although hyperventilation and hypersensitivity to changes in the partial pressure of carbon dioxide in arterial blood (arterial PCO_2) have been proposed as mechanisms involved in the symptoms of panic attacks, the exact role, if any, of hyperventilation has remained obscure (1, 2). This study was designed to test the hypothesis that panic disorder is associated with greater sensitivity of cerebral arteries to changes in arterial PCO_2 by measuring basilar artery blood flow with transcranial Doppler ultrasonography before and during hyperventilation. During the study, two patients with panic disorder were identified who had extraordinary reductions in basilar artery flow velocity during hyperventilation associated with substantial neurological symptoms. These two patients were treated with nimodipine, a centrally active calcium channel blocker that selectively dilates cerebral arterioles and limits calcium influx in CNS neurons (3). Both patients had normalization of basilar artery flow velocities and pulsatility during hyperventilation and marked improvement in symptoms in response to nimodipine.

METHOD

Nine patients meeting *DSM-III-R* criteria for panic disorder and nine healthy comparison subjects of similar age and sex were studied by transcranial Doppler ultrasonography before and during hyperventilation by using a Biosound Genesis II vascular ultrasound unit with transcranial Doppler capabilities (4). Two of the

patients with panic disorder were taking tricyclic antidepressants and the rest were drug free. All subjects gave informed consent. The basilar artery was insonated through the foramen magnum at a depth of 80–85 mm. Results are expressed as the mean flow velocity in centimeters per second and as the pulsatility index. The pulsatility index is equal to the peak systolic velocity minus the final diastolic velocity divided by the mean velocity. Generally, an increase in pulsatility index is an indication of increased vascular resistance distal to the segment of artery sampled by ultrasound. Hyperventilation was performed until a stable, minimum basilar flow velocity was achieved. This usually occurred within 60–90 seconds. Differences between patients and comparison subjects were analyzed by using a group *t* test or a two-factor analysis of variance with repeated measures as appropriate.

RESULTS

There were no significant differences between the nine patients with panic disorder and the nine comparison subjects in age (mean=40.1 years, SD=9.6, versus mean=38.4, SD=9.6, respectively), in baseline mean basilar artery flow velocity (mean flow velocity) (38.1 cm/sec, SD=12.5, versus mean=40.4 cm/sec, SD=6.0), or in baseline pulsatility index (mean=0.85, SD=0.16, versus mean=0.85, SD=0.12). As shown in figure 1, hyperventilation produced a significantly greater reduction in basilar artery flow velocity in patients with panic disorder than in comparison subjects (62% versus 36%) and a much greater increase in the pulsatility index.

Two patients were found to have a greater than 80% reduction in basilar artery mean flow velocity during hyperventilation. The histories of these patients are presented here. Each was treated with 30 mg of nimodipine orally three times per day. Repeat transcranial

nial Doppler studies were performed after 4 weeks of treatment.

Case 1. This 44-year-old man began to have unexplained syncope in adolescence. The spells resolved when he was a young adult but returned in conjunction with a severe anxiety disorder about 5 years ago. They reached a peak frequency of 5–7 spells per day of syncope or pre-syncope, each preceded by a sense of impending doom, vertigo, tachycardia, and diaphoresis. He underwent extensive evaluations, including cardiac monitoring, cardiac catheterization, carotid duplex ultrasonography, magnetic resonance imaging (MRI) studies of the head, and three EEGs. The results of all of these tests were normal. His spells had been treated unsuccessfully with a variety of medications including diazepam, doxepin, phenytoin, divalproex sodium, primidone, verapamil, clonidine, propranolol, and acetazolamide. Other history of note included premature birth (32-week gestation), classic migraine head-

aches at least once per week, chronic daily headaches, and hypertension. Results of the neurological examination were entirely normal.

Case 2. This 37-year-old man had a 10-year history of panic attacks that occurred 1–3 times per day. During this same period he experienced recurrent paresthesias, primarily in the left leg but also in the right leg as well as in the hands and neck. Extensive evaluations over the last 10 years have included multiple nerve conduction studies and EMGs, somatosensory evoked potentials, MRI studies of the brain and entire spine, a spinal fluid examination, metabolic testing for a variety of muscle diseases, a muscle biopsy, and consultations with at least five neurologists. Results of all tests have been normal. His past medical history was otherwise unremarkable, and results of the neurological examination were normal. He was taking no medications.

Both of these patients had low baseline basilar mean flow velocity (table 1); their baseline values were lower than those of any other patients or comparison subjects. Both had a greater than 80% decrease in flow and a very large increase in pulsatility during hyperventilation. After 4 weeks of treatment with nimodipine, the basilar mean flow velocity and pulsatility index responses to hyperventilation of both patients had returned to normal. Patient 1 had complete relief from his syncopal spells within 2 days of the onset of treatment. After 4 weeks of treatment, he decided to stop taking nimodipine because he felt that his chronic daily headaches were worse. However, his spells returned and he insisted on taking nimodipine again. Patient 2 also noted a marked decrease in the frequency and severity of his panic attacks as well as in his long-standing paresthesias.

An additional patient with more typical cerebral vasoreactivity (50% reduction in basilar flow velocity after hyperventilation) was treated with nimodipine. For this patient, nimodipine caused absolutely no change in either baseline or posthyperventilation flow velocity, pulsatility, or the frequency, quality, or severity of her panic attacks.

DISCUSSION

The nine patients with panic disorder as a group tended to have an exaggerated reduction in basilar artery blood flow during hyperventilation compared with comparison subjects. Not all of the patients in this study had greater responses than comparison subjects, but those who did tended to be the ones who developed neurological symptoms during their attacks. This relative cerebral ischemia during hyperventilation is probably not the fundamental cause of panic attacks but, rather, may be the mechanism responsible for some of the associated symptoms that reinforce the sense of panic.

The effect of nimodipine in normalizing blood flow responses to hyperventilation and ameliorating neurological symptoms in two patients was striking. Nimodipine readily crosses the blood-brain barrier and

TABLE 1. Effect of Nimodipine on Basilar Artery Flow Responses to Hyperventilation in Two Patients With Panic Disorder

Condition and Patient	Mean Flow Velocity			Pulsatility Index		
	Velocity (cm/sec)		Change (%)	Index		Change (%)
	Baseline	After Hyperventilation		Baseline	After Hyperventilation	
Before Nimodipine						
Patient 1	29	5	-83	1.03	5.60	443
Patient 2	26	5	-81	1.04	4.80	361
After Nimodipine						
Patient 1	34	23	-32	0.94	1.70	80
Patient 2	42	21	-50	0.93	2.38	156

acts on cerebral neurons to limit influx of calcium ions. This is the presumed mechanism by which nimodipine lessens ischemic damage after subarachnoid hemorrhage and stroke (5) and slows the progression of some organic dementias (6). The possibility that nimodipine is working on the symptoms of panic attacks by direct effects on CNS neurons, therefore, cannot be excluded. However, since nimodipine is also a potent and selective dilator of cerebral arteries, a more important site of action in panic disorder is likely the smooth muscle of cerebral arteries. Verapamil, a nonselective calcium channel antagonist that does not cross the blood-brain barrier, has previously been shown to have a modest beneficial effect in panic disorder (7), supporting a vascular site of action for these agents.

The two patients who responded to nimodipine in this study had extraordinary responses to hyperventilation and consequently had associated neurological symptoms that were more remarkable than most patients with panic disorder. Although the responses of these two patients to nimodipine were dramatic both subjectively and objectively, a more typical patient did not respond to nimodipine, suggesting that only a sub-

set of patients with panic disorder and severe hyperventilation-induced ischemia might benefit from nimodipine or other centrally active calcium channel antagonists.

Accumulation of Fluoxetine and Norfluoxetine in Human Brain During Therapeutic Administration

Perry F. Renshaw, M.D., Ph.D., Alexander R. Guimaraes, B.S., Maurizio Fava, M.D., Jerrold F. Rosenbaum, M.D., Justin D. Pearlman, M.D., Ph.D., James G. Flood, Ph.D., Patricia R. Puopolo, B.S., Katherine Clancy, B.A., and R. Gilberto Gonzalez, M.D., Ph.D.

In vivo ^{19}F nuclear magnetic resonance spectroscopy was used to measure the brain concentration of fluoxetine and norfluoxetine in five patients with obsessive-compulsive disorder and three with major depression. The mean brain:plasma ratio of the parent drug plus the metabolite was significantly elevated to 2.6 ($SD=1.0$) (95% confidence interval=1.9–3.3). This accumulation may have implications for understanding both the therapeutic and the toxic effects of fluoxetine.

(Am J Psychiatry 1992; 149:1592–1594)

The potential that in vivo nuclear magnetic resonance spectroscopy (MRS) holds for research in psychiatry has been the subject of recent reviews (1, 2). From a psychopharmacological perspective, MRS offers a means of noninvasively measuring the brain levels of those drugs which are MRS-visible. These agents include lithium and psychotropic medications that contain fluorine. To date, in vivo brain resonances have been detected in human subjects taking lithium, trifluoperazine, fluphenazine, and fluoxetine (3–5). The rationale for this work lies in the hypothesis that a knowledge of the brain levels of these drugs may contribute to an understanding of both their therapeutic and their toxic effects. Unfortunately, except for lithium, it has been difficult to quantitate brain drug levels or to correlate these values with corresponding plasma levels. Additionally, reports of spectra derived from subjects taking fluorinated psychotropic agents have generally consisted of data from a single subject taking unusually high doses of medica-

tion (e.g., 120 mg/day of trifluoperazine [4] and 350 mg/17 days of fluphenazine decanoate [5]).

Fluoxetine is a serotonin reuptake inhibitor that has been used successfully to treat major depression, obsessive-compulsive disorder, and bulimia. Both fluoxetine and its long-lived active metabolite, norfluoxetine, are trifluorinated. We used ^{19}F MRS to measure the brain level of fluoxetine plus norfluoxetine in eight patients with major depression or obsessive-compulsive disorder. In each patient, the brain level of fluoxetine plus norfluoxetine was several times higher than the plasma level.

METHOD

Our experimental protocol was approved by the human subjects committee of our hospital, and informed consent was obtained from each subject before his or her participation. Eight subjects took part in the study. All had been taking fluoxetine for a minimum of 3 months (mean=13 months, $SD=6$), and none had a dose change within 4 weeks of the study. Four subjects were taking 60 mg/day, three were taking 80 mg/day, and one was taking 100 mg/day of fluoxetine. Five patients had a *DSM-III-R* diagnosis of obsessive-compulsive disorder, and three had a *DSM-III-R* diagnosis of major depression. The patients' mean age was 34 years ($SD=8$); four were men and four were women. Four patients were taking at least one other medication (two were taking clonazepam, one was taking lithium, and one was taking methylphenidate). The clinician of each patient felt that the patient had improved markedly in response to fluoxetine.

A commercially available 1.5 Tesla whole body imager was used to collect in vivo spectra with a home-

Presented in part as a work in progress at the tenth annual meeting of the Society for Magnetic Resonance in Medicine, August 1991. built, 21-cm-inner-diameter, cylindrical head coil tuned to 60.1 MHz. Each patient was positioned so that only the upper half of his or her head (to the tip of the nose) was within the sensitive volume of the coil, and the magnet was shimmed on the water proton resonance to within 20–30 Hz over the sampled volume. A nonselective 90° pulse was used with a repetition time (TR) of 2 seconds, and 300 acquisitions were averaged over a 10-minute period in collecting ^{19}F spectra. For three of the eight patients, two independent measurements separated by a period of 30 minutes were made to evaluate the reproducibility of the technique.

Brain concentrations were calculated by comparison of the integrated intensity of the in vivo resonance with that arising from a 1450 cm³ cylindrical phantom containing 8.8 mg/liter of fluoxetine in 140 mM of sodium chloride (3, 4). The intensity of the phantom resonance was measured immediately after completion of the clinical study. The in vivo resonance was assumed to be derived primarily from the brain. Brain volumes for each subject were calculated from T₁-weighted axial images by using a volumetric image analysis program developed in-house; the estimated accuracy of this program for objects the size of a whole brain is plus or minus 5% at one standard deviation (unpublished data). The average total brain volume (cerebrum, cerebellum, and brain stem to the base of the pons, including ventricles) was 1360 cm³ (SD=170) for these eight subjects. The single observed resonance was thought to arise predominantly from both fluoxetine and norfluoxetine; pure samples of each had identical chemical shifts at high field (376 MHz). With TR=2 seconds, the phantom resonance was 73% of the fully relaxed value while brain resonances did not change consistently with TR=1, TR=2, or TR=4 seconds in two subjects.

Blood samples were collected at the time spectroscopy was performed. Plasma levels were measured by a commercial laboratory using gas chromatography with electron capture detection; this assay is said to be reproducible to within 13% at one standard deviation for both fluoxetine and norfluoxetine given the range of values obtained in this study. The concentration of fluoxetine in the phantom was determined by using high performance liquid chromatography with a photodiode array detector. This assay was performed in-house to correct for possible artifacts arising from the lack of plasma in the sample; duplicate analysis yielded concentrations of 8.7 and 8.9 mg/liter of fluoxetine, respectively.

RESULTS

Figure 1 outlines our results. Calculated brain concentrations of fluoxetine and norfluoxetine were 2.6 times higher than corresponding plasma levels. The difference between brain and plasma levels was statistically significant when a two-tailed paired *t* test was applied (*t*=5.59, *df*=7, *p*<0.0008).

Daily dose correlated more closely than plasma level

FIGURE 1. Plasma Versus Brain Drug Concentrations of Fluoxetine Plus Norfluoxetine in Eight Patients Receiving Different Doses of Fluoxetine^a

^aFor the correlation between plasma and brain drug level, *r*=0.58, *df*=7; for the correlation between daily dose and brain level, *r*=0.82, *df*=7. Mean ratio of brain to plasma drug level=2.6 (SD=1.0) (95% confidence interval=1.9–3.3).

with calculated brain levels (figure 1). The poor correlation between plasma and brain levels was disproportionately affected by values obtained from one of the eight patients whose brain level was 4.9 times higher than her plasma level. When data from this patient are excluded, the correlation coefficient between plasma and brain levels improved (*r*=0.82, *df*=6). It is unclear why the data from this one patient are so divergent; unfortunately, she refused to undergo repeat MRS or to allow a repeat determination of her plasma drug levels.

For the three patients who underwent repeated MRS measurement, duplicate values of brain concentration varied by 2%, 4%, and 9%.

DISCUSSION

Our results are limited by both clinical and technical factors. At a clinical level, we were concerned with being able to maximize the reproducibility of our brain measurement. Therefore, we sought to study individuals taking a range of relatively high doses of fluoxetine, which resulted in greater intensity of the detected resonance and allowed us to make measurements that were reproducible to within about 10%. However, in so doing, we ended up studying a clinically heterogeneous population and thus are unable to comment on whether the uptake of fluoxetine varies with diagnosis.

Technically, our results are limited by at least three factors. First, the low sensitivity of the MRS technique requires that data must be collected over an extended period of time (approximately 10 minutes). To increase the accuracy of our measurement by a factor of two with addi-

tional signal averaging, the patient would have to remain in the magnet for approximately 40 minutes.

Second, our results are influenced by the fact that spectra were collected without the use of a technique for spatial localization (1, 2). Thus, the assumption that the observed signal derives entirely from the brain neglects the contributions from the ventricular CSF and the surrounding extracranial tissues but assumes that the blood within the cerebral vasculature contributes to the observed resonance. Fortunately, the CSF in man is known to contain very low concentrations of both fluoxetine and norfluoxetine (6). In addition, there is relatively little extracranial soft tissue on the upper half of the head (the only region from which the signal was collected given the placement of our coil), so these contributions should produce a relatively minor elevation of the calculated brain level. On the other hand, since the calculated brain concentration of fluoxetine and norfluoxetine is higher than the corresponding plasma concentration, including the cerebral vasculature within the brain volume would tend to lower the calculated brain level slightly.

A third factor that affects our results is the assumption that the observed resonance is derived solely from fluoxetine and its long-lived active metabolite, norfluoxetine. In fact, other inactive metabolites that contain fluorine may also contribute to this resonance. There is relatively little published information on the tissue distribution of fluoxetine and its metabolites. However, in the pregnant rat, fluoxetine and norfluoxetine account for 47%–93% of the radioactive material recovered from maternal tissues in the 24 hours following a single injection of ^{14}C -labeled fluoxetine (7). After multiple doses, it is likely that fluoxetine and norfluoxetine, being both nonpolar and long-lived in comparison with their inactive metabolites, would be present at an even greater relative proportion.

Despite the limitations noted, our results are consistent with data derived from animal experiments. In the rat, brain concentrations of fluoxetine and norfluoxetine are several times higher than plasma concentrations following the administration of a single dose of fluoxetine (8). We are not aware of any published data on the concentration of fluoxetine or norfluoxetine in animal brain after chronic drug administration. How-

ever, accumulations of the tricyclic antidepressants clomipramine, imipramine, desipramine, and protriptyline are all roughly five to 20 times higher than plasma levels after chronic administration to rats (9). This is generally ascribed to high lipid and protein binding as well as to the synaptosomal concentration of these protonated basic drugs (10).

Although fluoxetine is thought to work on the basis of its serotonin reuptake inhibition, it may be that its apparent accumulation *in vivo* also contributes to both its therapeutic and its toxic properties. Further work will be needed to confirm these preliminary findings and to assess their significance.

Severity of Cocaine Dependence as a Predictor of Relapse to Cocaine Use

Roger D. Weiss, M.D., Margaret L. Griffin, Ph.D., and Cathryn Hufford, B.A.

The severity of cocaine dependence of 39 hospitalized patients was assessed by administering the Structured Clinical Interview for DSM-III-R. No significant relationship was found between severity of cocaine dependence and cocaine use at 3-month follow-up. These findings suggest that severity of cocaine dependence may be a poor predictor of relapse to cocaine use. (Am J Psychiatry 1992; 149:1595-1596)

The concept of the dependence syndrome, initially proposed to describe clinical features of alcoholism (1), has been expanded to include patients dependent on other drugs (2; *DSM-III-R*). A central tenet of the dependence syndrome concept is that clinical characteristics occur along a continuum of graded levels of severity (3). Thus, *DSM-III-R* criteria for psychoactive substance dependence include three categories of severity: mild, moderate, and severe. This classification scheme has two limitations, however. First, the boundaries between these categories of severity have not been clearly delineated. Second, although empirical studies have suggested that severity of alcohol dependence is a relatively good predictor of clinical outcome (4, 5), there has been little analogous research on drug dependence. Indeed, Babor et al. (5) found severity of dependence to be a good predictor of outcome in alcoholics but not in opioid addicts. Since we are aware of no studies of this subject in patients dependent on cocaine, we undertook a study of the relationship between severity of cocaine dependence and 3-month treatment outcome.

One-way analysis of variance (ANOVA) was used to assess the relationship between outcome and interval variables. Chi-square analysis was used in the assessment of the relationship between outcome and nominal variables.

METHOD

Data were collected from 52 patients hospitalized for treatment of cocaine dependence, which was diagnosed

by using the Structured Clinical Interview for DSM-III-R (SCID) (6); all patients gave informed consent. We eliminated from our analysis seven patients who had another axis I diagnosis that antedated their substance use disorder because comorbid psychopathology may influence treatment outcome in drug-dependent patients (7, 8). Six subjects were lost to follow-up. Our final study group thus consisted of 39 patients.

Severity of cocaine dependence was measured as a function of the number of criteria met for that diagnosis in the psychoactive substance use disorders section of the SCID, which was generally administered during the second week of hospitalization. A patient had to meet at least three of nine possible criteria to be given a diagnosis of dependence on a particular drug. Rather than using the subjective distinctions among mild, moderate, and severe dependence listed in *DSM-III-R*, we measured severity according to the number of diagnostic criteria met. For example, we considered a patient who met six criteria to have more severe dependence than a patient who met five criteria.

Follow-up assessments included monthly administration of the Addiction Severity Index (9), urine toxicological screens, and weekly substance use questionnaires. A repeat SCID was obtained at 3 months.

We divided treatment outcome into three categories: 1) total abstinence, 2) a slip, which we defined as having used cocaine on 1-3 days in the previous 3 months (i.e., 1 day a month or less) but not using cocaine at the time of the 3-month assessment, and 3) relapse to cocaine dependence.

RESULTS

The study group was predominantly white (N=34, 87%) and employed (N=27, 69%), with a slight preponderance of men (N=21, 54%). The patients had used cocaine for a mean of 8.8 years and had previously engaged in inpatient treatment a mean of 1.2 times. Twenty-one (54%) of the patients were predominantly intranasal users, 15 (38%) used cocaine primarily by

TABLE 1. Relationship of Severity of Cocaine Dependence to 3-Month Outcome in 39 Hospitalized Patients^a

Outcome	Number of Cocaine Dependence Criteria Met ^b	
	Mean	SD
Abstinence (N=24)	7.1	1.3
Slip (≤ 3 uses of cocaine) (N=6)	7.3	1.0
Relapse to cocaine dependence ^c (N=9)	8.0	1.2

^aF=1.67, df=2, 38, n.s.^bBased on DSM-III-R criteria for cocaine dependence in the psychoactive substance use disorders section of the SCID.^cNo patients relapsed to dependence on another drug (including alcohol) in the absence of cocaine use.

smoking, and three (8%) were intravenous users. The patients were currently using a mean of 16.7 g of cocaine per week and had spent, on average, \$7,250 on cocaine during the previous 6 months. There was no significant relationship between any of these cocaine use variables and 3-month outcome.

SCID data revealed that most of the patients (N=32, 82%) met criteria for at least one other current substance use disorder, particularly alcohol abuse or dependence (N=23, 59%). Among the patients with both cocaine dependence and alcohol abuse or dependence, 11 (48%) met criteria for a third substance use disorder. Subjects lost to follow-up were determined to be no different from available subjects with regard to sociodemographic characteristics, substance use histories, or number of SCID criteria met for cocaine dependence.

The mean number of SCID criteria met for cocaine dependence was 7.4 (SD=1.2) (range=4–9). As shown in table 1, ANOVA revealed no significant relationship between the number of criteria met and 3-month outcome. Grouping patients who had used cocaine three or fewer times during the 3-month period with abstainers, relapsers, or by themselves did not affect this result.

We reanalyzed our data by categorizing patients as having low, moderate, and high levels of severity. We measured severity in two ways according to the number of criteria they met: 1) mild=4 or 5 criteria, moderate=6 or 7 criteria, and severe=8 or 9 criteria, and 2) below the median=4–6 criteria, median=7 criteria (also the mode), and above the median=8 or 9 criteria. Neither measure of severity was significantly related to outcome.

DISCUSSION

Our data suggest that either 1) counting the number of DSM-III-R criteria met for cocaine dependence is an inadequate measure of severity or 2) severity of the cocaine dependence syndrome per se is not a good predic-

tor of future cocaine use. Our findings, combined with those of Babor et al. (5), who found that severity of alcohol dependence but not severity of opioid dependence was a good predictor of relapse, suggest that measures of severity of dependence may be somewhat substance specific.

Babor et al. (5) found that the drug severity score on the Addiction Severity Index was a significant predictor of the severity of the follow-up dependence syndrome in opioid addicts, although the correlation was not high. We did not report Addiction Severity Index scores in this study because Addiction Severity Index ratings of drug severity do not clearly distinguish among drugs. Because of the high rate of polysubstance abuse in our subjects, we focused specifically on the severity of cocaine dependence in this report.

One limitation of our study was the narrow range of severity scores in our subjects; since this was a hospitalized group of patients, most of the subjects had quite severe cocaine dependence. Moreover, findings in this study group of primarily white, employed patients may or may not be generalizable to cocaine-dependent patients in other settings. Future investigations that examine larger and more heterogeneous patient populations (e.g., minorities, unemployed patients, outpatients) are needed to help us make the measurement of severity of cocaine dependence a clinically useful tool in predicting clinical outcome and developing successful treatment strategies.

CHILDREN AND ADOLESCENTS

The Course of Life, vol. 4: Adolescence, edited by Stanley I. Greenspan, M.D., and George H. Pollock, M.D., Ph.D. Madison, Conn., International Universities Press, 1991, 519 pp., \$60.00.

Adolescence, one of the most crucial phases of development in the human cycle, is approached in this volume in a most interesting way, like a corridor with many doors. We have the contribution of Peter Blos reviewing the role of the father in pre-oedipal or early male adolescent development. Blos deals with the heretofore ignored early relationship between father and son, which provides the boy a particular sense of emotional and physical security and safety.

Further subdivisions and elaborations on the substages of adolescence are given new insights and knowledge. Thus we have the work of Judith Kestenberg on the transition from childhood to adolescence, followed by several papers that elaborate on the passage from late adolescence to early adulthood. This book contains important and controversial issues connected with the homosexual adolescent and his development. It would have enriched this area of the volume if other psychoanalytic researchers, such as Richard Freidman and Susan Coates, would have contributed.

Although there is overlap in the chronological substages, this text illuminates the issues that adolescence brings out in terms of potential for disturbance and psychopathology, such as the Hilde Bruch's concept of "escape from change" in her sleeping beauty metaphor. The book also focuses on the insights into developmental psychology provided by the study of adolescent delinquents, as illustrated by Shore and Massimo. There are some innovative detours into a discussion of the relationship between family dynamics and learning disorders and a discussion of career achievement, issues that have not been tackled in other comprehensive textbooks of adolescent development. Daniel Offer contributes normative perspectives and an important caution to avoid the previous decades' mistake of considering adolescence a period of heightened psychopathology.

One issue that I did not see developed as it deserves is the complex interplay between suicidality and adolescent stages. It is not included in the subject index. I am sure that many of the authors have much to say about this important topic from a psychoanalytically inspired developmental perspective.

I consider this volume a welcome complement to traditional descriptive psychiatry. In my opinion, it is impossible to really understand psychopathological syndromes in adolescence without having grasped in depth the subjective experience of adolescents in their psychological structures—the working schemata formulated by adolescents to deal with themselves and others. In summary, this book is an enriching source to be recommended to anybody interested in human develop-

ment in general and high school and college-age populations in particular.

PAULINA F. KERNBERG, M.D.
White Plains, N.Y.

Fundamentals of Child and Adolescent Psychopathology, by Syed Arshad Husain, M.D., F.R.C.P.(C), F.R.C.Psych., and Dennis P. Cantwell, M.D. Washington, D.C., American Psychiatric Press, 1991, 316 pp., \$45.00.

This book by Drs. Husain and Cantwell is a fundamental text of child and adolescent psychopathology. It is written for students of medicine and allied disciplines, not for specialists in child and adolescent psychiatry. The guiding framework for the description of the disorders in this book is APA's *DSM-III-R* classification system. In this system, disorders are first described phenomenologically and then are defined by inclusion and exclusion criteria. The system also emphasizes subtyping and differential diagnoses. The conceptual implication of such a system is that these clinically defined disorders will differ in demographic factors such as age, sex, and social class; in prevalence rates; in morbid risk rates and life expectancy; and in outcome and response to different forms of therapeutic intervention.

The text is divided into three sections. The first, Introduction, comprises five chapters that discuss the history of child psychiatry; normative development focused on attachment and bonding, Piaget's cognitive development, Erikson's psychosocial development, gender identity, moral development, and temperaments; principles of assessment and tools for the assessment; purposes of and a theoretical approach to classification and elements of the *DSM-III* system of diagnostic classification; and types of therapeutic interventions and principles of psychopharmacotherapy in child psychiatry.

The second section, Disorders, consists of 11 chapters focused on childhood and adolescent psychiatric disorders, including disruptive behavior disorders, anxiety disorders, eating disorders, tic disorders, elimination disorders, speech disorders not elsewhere classified, mood disorders, suicide, parasomnias, developmental disorders, and other disorders such as elective mutism, identity disorder, and reactive attachment disorder. For each disorder there is a brief description or discussion of the clinical picture, natural history, etiology, epidemiology, differential diagnosis, and treatment.

The third section, Psychiatric Symptoms, Chronic Conditions, and Special Problems, contains three chapters dealing with common psychiatric symptoms that are not part of any psychopathological disorder per se (e.g., thumb and finger sucking, masturbation), psychiatric symptoms associated with chronic medical conditions (e.g., asthma, cancer, and deafness), and special problems such as physical and sexual abuse and death and dying. The meanings of the symptoms in these conditions are briefly discussed, and useful managements are described.

Although neurobiological studies have not been validated, this book refers to some recent developments in genetics, neurochemistry, neuroimaging, and neuropharmacology in child and adolescent disorders. These developments and the therapeutic interventions of each disorder are not discussed in great detail, but an overview is given for each disorder, followed by references for further reading. It is somewhat disappointing that more recent data were not incorporated; there are no clinical references past 1989, and many of the references cited were published in the 1950s, 1960s, and 1970s. This certainly does not give one an impression that child and adolescent psychiatry is a fast-growing medical and behavioral science.

The book is well written, and the authors are to be congratulated on the massive amount of careful work that has gone into its production. It has a great deal to offer the beginner as a good first step toward an understanding of the fundamentals of child and adolescent psychopathology. If the reader wants an easy-to-read book that reviews and integrates the research literature, this is an excellent book to have until the *DSM-IV* classification is adopted.

PSYCHOANALYTIC VIEWS

The Fundamentals of Psychoanalytic Technique, by R. Horacio Etchegoyen; translated by Patricia Pitchon. New York, Brunner/Mazel, 1991, 863 pp., \$100.00.

This unique and very long book, written by a brilliant man and an astute clinician, poses a reading task similar in my mind to Tolstoy's *War and Peace*. Of course Etchegoyen would say that my association to *War and Peace* reflects my ambivalence about his book, and he would be correct. The book is interesting and erudite and packed with many clinical insights and theoretical speculations, but as a reviewer I must also point out some of its serious flaws.

The book comprises Etchegoyen's informal talks to his students interspersed with his reading notes, so it presents a mixture of fascinating clinical anecdotes, personal opinions, and very condensed reviews of some extremely difficult authors. One of the remarkable aspects of the book is that the authors reviewed are writers in several languages, and some of them will not be familiar to U.S. psychiatrists and psychoanalysts.

Etchegoyen is a prominent Argentine psychoanalyst and an important personage in international psychoanalysis. His writing makes it obvious that he has a complete grasp of the Kleinian theory he espouses and great clinical experience along with impressive intuitive skill. This book desperately needs editing because it is quite repetitious and many of the sentences are cumbersome. I do not know if this is a function of the translation or not, but the reader will have to be prepared to tangle with such syntactical catastrophes or obscure ambiguities as,

Since Winnicott never leaves out of consideration the genetic equipment of the newborn child, then inevitably the thought is that the child influences his environment (mother), with which we are already supporting the Freudian idea of complementary series that Klein utilizes, questioning at root the doctrine of environmental failure, which the child has nothing to do with. (p. 562)

As a third possibility, Money-Kyrle studies the orientation towards a confused base and takes Meltzer's (1966) paradigm, when the child confuses the mother's breast with the bottom that goes away and then with his own bottom, which he enters in a masturbatory act. (p. 777)

Eight hundred pages of this leave the reader exhausted. The historical and current literature reviews that appear in each section are obviously dictated directly from reading notes and not always well integrated with the text (for example, the reviews of Yorke on pages 400–401 and Caddini on pages 722–723). I do not believe the discussions of such important thinkers as Lacan and Bion can be understood by anyone who is not already familiar with these writers, and this is true of the reviews of a number of other thinkers that are interspersed throughout the book. The informal chatty style, when it appears, is very enjoyable, but it is not always clear whether Etchegoyen believes what the author he is reviewing believes.

The book is in essence a polemic for Kleinian psychoanalysis, and some parts, especially the case vignettes, are very well written and reveal Etchegoyen to be a clever, decent man and an outstanding psychoanalyst, but the appreciative audience for the book would have to be primarily experienced psychoanalysts. Even psychoanalytic candidates would have trouble with it because they do not have the necessary background to engage with Etchegoyen in his theoretical discussions.

The book really is two books in one. The first consists of Etchegoyen's review of the literature and theoretical discussions, and the second propounds his approach to the technique and practice of psychoanalysis. Both are extremely valuable, but the former requires much more reading background and knowledge than the latter.

Etchegoyen indulges himself in some extraordinary statements that are put forward without documentation, for example, "Ulcerative colitis . . . even in its most serious forms, is an illness that almost always responds satisfactorily to psychoanalysis" (p. 22). He also likes to throw in references to philosophers, which are both dubious in content and will be completely unintelligible to readers who are not familiar with the philosopher. For example, he tells us, "In this sense, if it is successful, analysis resolves dialectically Heidegger's three stases of time" (p. 91). Not only will this be meaningless to anyone who has not studied Heidegger's *Being and Time*, but I believe those who have studied *Being and Time* will disagree, because Heidegger's *ek-stases* of time are part of his ontological investigation, and he would not be willing to apply this to ontic studies such as psychoanalysis. It is not clear why the chapter by Klimovsky "Epistemological Aspects of Psychoanalytic Interpretation," was included in the book, since it ignores a vast literature on this topic and certainly does not contribute anything to understanding the fundamentals of psychoanalytic technique.

Etchegoyen's Kleinian orientation requires the reader to accept such speculations as those about the effect on an adult woman of her mother's nipple being cracked during her infancy or about the effect on a male patient of his mother's milk suddenly drying up when he was 2 months old. It might be felicitous to read Etchegoyen at his best by starting with the clinical cases presented on pages 287 and 363, which demonstrate his version of Kleinian psychoanalysis in action. If the reader cannot accept such speculations about the infant's experiences and their effect on the adult, then the reader will be unable to tolerate this book. In Cervantes' great novel, there are two paradigmatic characters in a dialectic, Don Quixote and Sancho Panza. The Kleinians with their wonderful imagi-

nation may be thought of as the Don Quixotes of psychoanalysis, and the American pragmatic ego psychologists may be thought of as the Sancho Panzas. The polemic between the two is a theme running throughout Etchegoyen's book, and he attempts to be fair to the Sancho Panzas, although clearly he is a Don Quixote, when he is not writing like Thomas Aquinas, as he does in chapter 8, his scholastic commentary on Freud's "The Dynamics of Transference."

Etchegoyen is a superb clinician and very conservative: "No intervention of the analyst is valid if it violates the rule of abstinence" (p. 13). He leans heavily on Bion's idea of *reverie*, a capacity for resonance with what the patient projects. Etchegoyen is a humane physician with good common sense and decency in his treatment of patients. He insists that there is no effect of tape recording and note taking during sessions, which I find puzzling, for just as he says that "transference exists in everything" (p. 83), I am sure he is well aware that countertransference exists in everything also.

Because Kleinians emphasize the intrapsychic fantasy life of the baby much more than the actual environmental factors, Etchegoyen cannot accept Kohut's basic contention that parental failure of empathy is the crucial pathogenic factor in narcissistic disorders. This is not to revive the incorrect argument against the Kleinians that they do not take into account environmental factors at all. In fact, the case histories on pages 287 and 363 hinge on postulated unfortunate environmental happenings. Etchegoyen also rejects the common complaint that Kleinians interpret too deep and too fast, which implies that Kleinians have no common sense. I think he is correct about this. In a book with many case vignettes I found only one (p. 547) where I thought Etchegoyen really missed what was going on.

I did not find Etchegoyen's explication of Racker's views to be intelligible, and I had the same problem with the long and tedious discussion of Money-Kyrle's theories, which takes up much of chapter 59. On the other hand, I found the discussions of projective counteridentification, negative therapeutic reaction, acting out, and Bion's "reversible perspective" to be excellent and clinically very valuable. Etchegoyen's emphasis on separation anxiety, which comes up repeatedly in the latter part of the book, is very important for clinicians. I found the attempt to differentiate between projective identification and "adhesive identification" as a form of "very narcissistic" (p. 574) identification provocative but questionable. One emerges from Etchegoyen's book with an increased appreciation of the work of Bion, since Etchegoyen seems to have thoroughly integrated Bion's thinking into his technique. This is especially true in the discussion of "the container/contained theory," but readers will have to accept Bion's Kleinian insistence that "we are born with a *preconception* of the breast" (p. 587).

In spite of his reliance on Popper, Etchegoyen makes the valuable clinical point that "the analytic process continually tests the theories the analysand has about himself and leads him to confront these with the content of reality" (p. 683). This is an excellent way to look at the concept of insight, and it leads into a discussion of the obstacles to insight as Etchegoyen lists and discusses them—acting out, negative therapeutic reaction, and reversible perspective.

The reader will have to decide whether this book accomplishes what Etchegoyen calls its "most persistent purpose," which is "to draw a clear distinction between psychoanalysis and any hidden or overt way of psychotherapy, through a model that respects the internal life of the analysand and abstains rigorously from suggestion and direct action, however beneficial it may appear to us" (p. 803). The book is a unique

and fascinating personal statement by an extraordinary man, but it is not to be considered a basic book on the technique and practice of psychoanalysis comparable, for example, to the well-known work of Greenson (1) or the meticulous text by Thomä and Kächele (2). It is best read as a brilliant example of an experienced Kleinian analyst at work, interspersed with a review of the international literature at an advanced level. Anyone who is willing to yield at least temporarily to the quixotic Kleinian imagination and is willing to struggle with the difficulties of this text is certain to emerge with an improvement in their clinical work and with some fresh ideas on their theoretical orientation. I hope this book will soon appear in a second and rigorously edited edition, which will make it accessible to the much wider audience that it well deserves.

Evanston, Ill.

Pain and Passion: A Psychoanalyst Explores the World of S & M (Sadomasochism), by Robert J. Stoller, M.D. New York, Plenum, 1991, 306 pp., \$24.95.

This book is a masterpiece. It is an informative contribution to the science of human behavior. Dr. Stoller, who died last year, was Professor of Psychiatry at the University of California, Los Angeles, a psychoanalyst, and an authority on gender identity, erotics, and perversions. With courage and curiosity, in this book he presents personal observations of strange sexual human practices, some places where they occur, and their operations.

In the preface, he relates how he entered the natural habitat of practitioners of bondage and discipline to learn in depth about what is "normally" considered repugnant and bizarre human behavior. He emphasizes the need while reading this book to be alert to what is true and valid.

The book contains five parts. The first, Introduction, consists of three chapters: "Consensual S.M. Perversions," "The Term Perversion," and "Methodology." In discussing ethnography Dr. Stoller says, "I want to do something risky—in pulling the decent reader to primitive raw data" about Sadomasochism. He insists that natural observations are essential before deciding on psychoanalytic theory. The place for observation is the bondage and discipline establishment to obtain information from owners, employees, habitués, sadomasochism therapists, and pornographers.

The term "perversion," according to Dr. Stoller, involves genital excitement by means of pain. He presents a long classified list of perversions and cautions that true dangers must be prevented in the theatrical increase of excitement. This entails mutual trust of partners who know and observe the rules of dehumanization and avoid nonconsensual acts like rape. Dr. Stoller points out that the participants appear "sick" in a single aspect of sexual life but are otherwise "normal."

In the chapter on methodology Dr. Stoller tells us he worked without a plan. His purpose was to get acquainted with his surroundings, ask people what they think, and stimulate them with interesting questions. The accuracy of their responses cannot be checked. He audiotaped all interviews, wrote up the

material, let the people involved read and correct his material, reviewed the literature, and cross-checked. He questions whether this is scientific.

Part two, *Ethnographic Joys*, contains four chapters: "Entree," "Dominatrix and Slave," "An Island for Dr. Moreau," and "Ladies Club." In the first chapter, Dr. Stoller says that the police provided entree to legal bondage and discipline clubs. Dr. Stoller learned that advertisements for bondage and discipline appear in the press. Some establishments offer tours for the customer, and tours were arranged for him. He describes one house he visited as looking like a home with special rooms made up theatrically with instruments of torture. Dr. Moreau, the owner, says that his customers are just folks playing out erotic fantasies without orgasm and that he is committed to erotic pleasure and has even tried to obtain research grants for such studies. In this house, Dr. Stoller sees a woman in diaphanous clothes prepared to be beaten by a man or to beat him. He tells us that the death instinct or aggression turned inward is insufficient to explain such practices. Max, the owner of another bondage and discipline club, considers it a business. Dr. Stoller emphasizes that he is informed only of surface behavior, not what people are thinking in depth. He describes Tammy, a sexy female professional who shows him instruments of bondage, torture, and degradation. While speaking to him, she pinches his nipple to demonstrate her talent, but he protests and she stops. Tammy tells him she is dominant toward males but is capable of switching to being submissive, that Stanley is her slave, that she slaps his face and he loves it. Candy, a seductively dressed childlike female, shows off stripes of having been beaten.

In the chapter on dominatrix and slave Dr. Stoller describes listening to a videotape and his concern about what the truth might be. Further information about Tammy's dominance reveals her as a femme fatale in spike heels looking for submissive males for bondage and discipline. Slaves do her chores and sexual biddings, receive her punishment, and worship her. She is involved with fetishes, both soft (silk, satin, and nylon) and hard (leather, spandex, and rubber). Her object is to degrade men, tease them, overpower them, and turn them on, all without orgasm. If the consensual agreement is violated by the customer, she threatens with a controlling admonition, "If you do that again, you'll lose your cock," and they stop. Excitement comes from the act of submission and is not considered sexual.

In another chapter in this section, Dr. Moreau is described as a philosopher and theoretician referred to as "sir." He and several of his employees provide information. For instance, Bart loves sadomasochism because of its honesty and feels that it is less hostile than sexuality expressed among "normals." Honey declares that the feminine erotic preference is to be submissive to a dominant male. She insists that all women look for this dominant male. Employees of the club are selected carefully. They must have above-average intelligence, and hookers are excluded. The customers are not freaks. Female clients are articulate and assertive and include doctors, lawyers, designers, and executives. They seek submissive bondage, especially nipple clamps, for excitement. There is an alarm system to which the staff respond immediately to protect female clients against aggressive men who may violate consensuality. The staff can be rough in their assistance. Male clients include judges, lawyers, doctors, and police officers. Some may encourage their wives and girlfriends in bondage and discipline practices, and the hope is that they will come ultimately to rent a room.

In "Ladies Club," Dr. Stoller tells us that Dr. Moreau does not let him talk with some women who want to talk to him.

Dr. Moreau is also unforthcoming regarding details and explanations of his philosophy. Max, too, is guarded and uneasy and presents superficial undynamic information. A third discipline and bondage club is owned by two women who talk about the glories of bondage and discipline and defensively try to elevate their self-esteem. In addition to the usual instruments of torture, this club contains cages for further dehumanization. The setting is noisy, cluttered, public, and uncomfortable, with competing informants resulting in incoherent dictation. They tell Dr. Stoller that Dr. Moreau is crazy, that he can no longer tell fantasy from reality. The atmosphere is whorish and fetishistic, operated by smart women who say they are helping people. Dr. Stoller wonders how to tell truth from fiction, whose report to believe, and what has been forgotten, omitted, or discounted as unimportant in providing narrative descriptions.

Part three, *Recitativos*, consists of three chapters, "How One Plays," "Dominatrix Redone," and "Dominatrix." In the first of these chapters Dr. Stoller declares that the main purpose of the book is to determine criteria of validity. His informant, Ron, impresses him as articulate, insightful, and honest. Ron is a writer, is in therapy for manic-depressive disorder, and likes pornographic films. He declares that life in the clubs is unstable, that entrepreneurs take advantage of vulnerable employees. Actually, all of the clubs are houses of prostitution, but the women do not consider themselves whores. They are poor, have little education, are damaged psychologically, and have low IQs. Clients lie and are perverts and kinks, but most are scared and respectful. The police have to be called in to control dangerous clients.

In "Dominatrix" Stoller discusses Tammy again. She is open, intense, erotic, manic-depressive, suicidal, and has a need to be hurt. She lives with Ron, who fulfills this need, and she is affectionate toward him in response. When she is bad to him, she begs him not to hate or abandon her. She trades sex for cocaine, and she likes being chained down so that she can overcome her cocaine binge. Ron turns her from dominant to submissive and he whips her while a client watches. She would like to be normal. Her family history is one of emotional disorder. During an interview of a male client, she determines his wishes and negotiates the cost. She sets up a slave set and does everything to hurt and humiliate him. When he screams theatrically, "I'm going to die," she induces more pain, pinching his nipples, and has an orgasm on his face. Shortly after, Tammy has a suicidal cocaine episode.

Part four, *S & M Porn*, consists of the chapters "Merlin of the Movies" and "Merlin Magus Magister." Merlin lives dangerously yet cautiously. He has been a high school teacher and does not look cruel. He writes, produces, directs, and performs with Ron and three women in pornographic films. The men feel that they are rebels against a straight society and enjoy forcing decent folk to discover their own pornographic propensities. It is all simulation and fantasy, a game of erotic day dreams and feelings that men cannot share with their mates. Can films seduce viewers? Intelligent people are attracted to sadomasochism, and they seek more variety in sex. In Ron's opinion, people in sadomasochism have no domestic violence to overcome. They have fantasies based on adult erotics, and pornographic production should be legal. Actress Vanessa declares that sex is her business and her task is to provide excitement and gratification for men.

In part five, *Conclusion: Ends and Starts*, Dr. Stoller presents thoughtful comments about the complexities of psychiatric work and the necessity to question whether what is reported by informants is to be trusted. Our object is to learn more than we know about perversions and to learn to judge

what is written. He suggests that perversion is an eroticized triumph over childhood traumata—a triumph over evil and self-deception.

Dr. Stoller made a fascinating house call to extend the work of Krafft-Ebing, Ellis, and Freud, and although he doubted the science of his work, I think he applied its major first step—observation. He exposed himself to a strange aspect of human behavior without fear of “catching it.” He did not actually see the bizarre in action, and maybe that is for the best. I am deeply impressed with his work, not only for medical reasons but for its forensic value. It should be studied by all mental health professionals and those legal minds interested in perversion. The final chapter certainly should be studied by students of science. The book contains a bibliography and an index. Read it.

TEXTBOOKS

The American Psychiatric Press Textbook of Neuropsychiatry, 2nd ed., edited by Stuart C. Yudofsky, M.D., and Robert E. Hales, M.D. Washington, D.C., American Psychiatric Press, 1992, 805 pp., \$95.00.

Neuropsychiatry is gradually coming of age. Its major aim has always been to link abnormalities in cognition, mood, and behavior with specific brain dysfunction. In the late 1960s and early 1970s, most study of neuropathologically caused disorders of behavior or intellect focused on aphasia, apraxias, amnesias, dementias, and complex partial seizure disorders (“temporal” and “frontal” lobe syndromes were often discussed in this latter context). These areas often fell under the rubric of “behavioral neurology,” which was largely rooted in relationships between structure and function based on neuroanatomical lesions and seemed more neurology than psychiatry. At this time, the nascent discipline of biological psychiatry, with its roots in psychopharmacology, the chemical “soup” of the brain, seemed a distant cousin. Biological psychiatry sought to explain more complex behavioral abnormalities and make pathophysiological inferences by reasoning backwards from the known biochemical actions of effective psychopharmacological agents. Students of one discipline seldom knew a comparable amount about the other.

As biological psychiatry became increasingly informed by an exploding neuroscience database in the 1980s, neuropsychiatry, still heavily based on clinical-anatomical correlations (and often small-scale anecdotal ones at that), seemed to be lagging behind. I purchased the first edition of this book shortly after its 1987 publication and found myself disappointed, though not surprised. It was heavily focused in clinical-neuroanatomical correlations and included little in the way of recent developments in neuroscience. As such, it resembled a smaller scale, far less comprehensive version of Lishman’s textbook *Organic Psychiatry* (1).

When I saw this second edition of *The American Psychiatric Press Textbook of Neuropsychiatry*, I was shocked, surprised, and delighted. Almost twice the size of the first edition with 15 totally new chapters and 10 chapters entirely rewritten by new authors (only eight original chapters remain and even these have been revised and updated), this is a totally new book. To begin with, the organization has changed substantially. From three sections, some with conceptually mixed

messages, it has gone to five crisp, orthogonal sections: 1) Basic Principles of Neuroscience, 2) Neuropsychiatric Assessment, which includes the bedside examination, neuropsychological testing, electrodiagnosis, and brain imaging (the epidemiology and genetics chapter, though superb, is out of place here and seems to belong back in the basic section), 3) Neuropsychiatric Symptomatology (this section should be labeled “Syndromes”), addressing disturbances in attention, sensation (pain), language, memory, mood, impulse and mixtures of these (delirium) in both pathophysiological and biochemical terms, 4) Neuropsychiatric Disorders, organized around etiologies such as infection, trauma, metabolic, stroke, tumor, and degenerative dementias, and 5) Neuropsychiatric Treatments, the only section still reasonably intact from the first edition (and one of its best).

An editorial board of superstars (Andreasen, Barondes, Bloom, Coyle, Cummings, Robinson, Snyder, and Tucker) obviously allowed more stringent peer review, and it shows in the overall scope, depth, and critical detail of each chapter. The citations at the end of each chapter are of unusually high quality and currency. Although each of the chapters is unique in its own way, there is a degree of redundancy throughout that allows for different perspectives on a specific topic. However, each chapter stands on its own as a comprehensive review. Throughout the book, pathophysiology from both gross anatomical and more microneuronal/transmitter perspectives is emphasized, and the solid clinical detail of the first edition is retained. This interweaving of the basic and clinical builds in a major strength. Most importantly, intelligent theoretical discussions of potential pathophysiological mechanisms in cases where brain pathology cannot be technologically demonstrated allows clinicians to “find their way in the dark” by refining their intuition and judgment about specific cases and syndromes where there may be a dearth of information.

In this edition, the 88-page, three-chapter section on basic principles of neuroscience replaces a single 35-page chapter in the first edition that reviewed concepts of neuronal transmission focusing on the classical transmitters circa 1980. Here, in chapter 1, stupendous illustrations supplement readable but not simplistic discussions of neuronal signaling, postsynaptic receptor mechanisms, sensitization, long-term potentiation, and neuronal growth and plasticity. Chapter 2 discusses the electrophysiology of sleep, arousal, and wakefulness, focusing on excitatory amino acids, second messengers such as calcium, and the role of early gene expression (c-fos and jun). Chapter 3 is a solid basic review of functional neuroanatomy based mostly on human lesion studies.

The section on assessment has done away with speculative attempts of the first edition to include “biomarkers” such as thyrotropin-releasing hormone testing and platelet receptors as part of the assessment battery and instead improved on its discussion of imaging. One can read in a brief, succinct section about the meaning and clinical significance of T₁- or T₂-weighted magnetic resonance images and find a careful, terse review of positron emission tomography findings related to the major psychiatric disorders. Magnetoencephalography is briefly discussed, and the uses and limits of EEG “brain mapping” are cogently reviewed. The bedside testing chapter is far broader in scope than before, although inclusion of assessment scales besides the Mini-Mental State Examination might have been helpful for the clinician.

In the third section, discrete syndromes are discussed from anatomical, physiological, and biochemical perspectives. Although the chapters are uniformly solid, the general organization of each is quite different, making the section itself appear disjointed when several chapters are reviewed in succession.

The extreme opposite would be *Harrison's Principles of Internal Medicine* (2), where symptoms are all reviewed based on the same general outline. This section, instead, strives to leave the individual stamp of each author on its chapters, which has its drawbacks. A particularly strong chapter is the one on delirium by Wise and Brandt. It has been updated considerably and is now more strongly data based, with studies rather than cases included wherever possible. As such, it is the best general review of delirium I have seen.

In the fourth section, specific neuropsychiatric disorders are reviewed. Many of these chapters were retained from the first edition. Among the stronger ones in that edition, they have been further updated and revised. In particular, the chapter on head trauma by Dr. Silver and the two editors, Dr. Hales and Dr. Yudofsky, considerably expands the discussion of clinical features and methods of assessment. Although it makes timely mention of the difficulty distinguishing past concussive versus posttraumatic stress disorder aspects of head injury, more discussion of this would have been useful. The chapter on cerebrovascular disease has also been further refined, and more clinical information and more background studies have been added. A section in the first edition on neuropsychiatric aspects of vitamins is now gone, which is too bad, although its relevance to the practicing clinician may have been limited. A new chapter on AIDS is timely and required reading for any general psychiatrist. In addition to basic virological mechanisms and a review of opportunistic CNS infections, it has an excellent discussion of the controversial area of neurocognitive deficits in early HIV infection, in which the authors, rather than drawing firm conclusions, provide a scholarly framework for analyzing the disparate results of individual studies in this area. The chapter on alcohol-induced disorders has, in addition to predictable discussions of both withdrawal and Korsakoff's syndrome, a more novel review of neuropsychological changes in alcohol abusers not suffering from Korsakoff's, which is quite clinically relevant. Despite its admirable scope, the chapter on epilepsy, in an attempt to go beyond the fairly straightforward, unambitious one in the first edition, strays too far from the data in places and relies too heavily on opinion, anecdote, and the introduction of acronyms. For the first time, schizophrenia takes its place among these other, more traditionally neurological disorders with its own chapter. Although the data reviewed are comprehensive and up-to-date, the conclusions are necessarily preliminary and vague ("the exact neuropsychiatry of schizophrenia remains a mystery"), suggesting that these more complex behavioral disorders, while theoretically the province of neuropsychiatry, will continue to stand somewhat apart from it.

The final section on treatment remains as before, solid, but also new and improved. A chapter on the psychology of neuropsychiatric disorders is outstanding, and a new one on family caregivers of afflicted patients is timely with the increasing research in this area. A single chapter on psychopharmacology is an impossible task that is reasonably well accomplished, especially since this topic appears in many other chapters with respect to given syndromes and disorders. Finally, a newly authored chapter on ethics and legal issues in psychiatry written by Robert Simon, editor of the *American Psychiatric Press Review of Clinical Psychiatry and the Law* series (3), is outstanding.

I have traditionally counseled residents and junior faculty members to avoid purchasing most textbooks. Although they often provide an easily accessible source of information, not infrequently the treatment of a given topic can be out-of-date, too superficial, overly weighted in the basic science or clinical

direction, idiosyncratically skewed by the author's own research or clinical interests, and lacking discussion of a key concept or area. In my mind, this book, though not perfect, is an exception. The editors are to be commended for bringing the field of neuropsychiatry up-to-date with the rest of neuroscience, while still making it wholly accessible to the practicing clinician. This was no easy task.

Inpatient Psychiatry: Diagnosis and Treatment, 3rd ed., edited by Lloyd I. Sederer, M.D. Baltimore, Williams & Wilkins, 1991, 431 pp., \$58.00.

This is the third edition of a valuable textbook first published in 1983. The fact that it is a third edition in less than 10 years attests both to its value to the field and the rapidity of change in psychiatry that necessitates frequent updating of standard texts. Like the previous editions, this version is divided into two major sections, one dealing with the diagnosis and treatment of specific diagnostic entities and the other with specific aspects of inpatient treatment.

Compared with the first edition, most of this volume is new material by new authors. Only six of the contributors to the first edition are represented in this revision. In section one, most of the same topics are included and an excellent chapter on HIV Infection by Marshall Forstein and Jay Baer has been added. In section two, new chapters by Bursztajn, Gutheil, and Cummins ("Legal Issues in Inpatient Psychiatry"), Schwartzberg and Kahane ("Occupational Therapy"), and Sederer ("Quality, Cost, and Contracts: Administrative Aspects of Care") are included.

Treatments such as psychotherapy, milieu, group, psychopharmacology, family work, and others are covered in each of the chapters in section one. Although this allows for a tailored discussion of approaches to each disorder, it also leads to redundancy. Some chapters are repetitious; for example, there is considerable overlap between the chapter on organic mental disorders in section one and the chapter on the clinical laboratory in section two. The inclusion of discussions of controversies in treatment for each disorder provides a forum for a broader look at the practice of hospital psychiatry.

This volume focuses on acute inpatient care and is probably more pertinent for psychiatrists and others working in private hospitals or on acute psychiatric units in general hospitals. It does not offer much for the treatment of the chronically ill public mental health patient. For example, discharge planning and aftercare planning are not discussed. Nor are the topics of water intoxication, posttraumatic stress disorder, or multidisciplinary treatment planning covered. The treatment plan has a single reference in the appendix to the chapter on the medical record. This refers to the team treatment plan as "the operational core of the chart and the veritable compass of the course of hospitalization" (p. 417). In view of the absence of

discussion of treatment planning elsewhere in this volume this is a hollow assertion. Accreditation issues are not mentioned, although quality assurance and utilization review are. The absence of a section on geriatric psychiatry is surprising and distressing in view of the fact that the elderly are one of the faster growing segments of inpatient populations. These are minor criticisms; to deal adequately with issues of importance to the public sector inpatient setting would require a book twice as long as the present one. Regardless, this is a useful book that deserves to be on the shelf of every psychiatrist who practices in a hospital setting.

ALCOHOLISM

Recent Developments in Alcoholism, vol. 9: Children of Alcoholics, edited by Marc Galanter. New York, Plenum, 1991, 350 pp., \$72.50.

The goal of this and previous volumes in this prestigious series is to examine subjects in alcoholism that are timely and challenging. This volume begins with a section entitled Genetic Predisposition to Alcoholism, which examines in detail a number of psychological and biological factors in individuals at highest risk. The second section reviews the fetal alcohol syndrome. Facts and medical syndromes are described in sufficient detail for the clinician and researcher. Estimates of the treatment cost to our society per year for fetal alcohol syndrome may be as high as \$53 billion. The third section of the book considers alcoholism and vulnerability to disease. Alcohol is known to suppress the immune system, making alcoholics vulnerable to many transmissible diseases. The final section reviews social and environmental issues with a special emphasis on the epidemiology and psychological characteristics of children of alcoholics and adult children of alcoholics.

The editor, Marc Galanter, has done a wonderful job of inserting considerable order into this volume. The four major sections are successfully introduced by a state-of-the-art overview. Henri Begleiter (Genetic Predisposition to Alcoholism), Donald Gallant (Fetal Alcohol Syndrome), David Van Thiel (Vulnerability to Disease in Relatives of Alcoholics), and Edward Gottheil and Jeannette Johnson (Social and Environmental Issues) conscientiously describe what is included in their section and why. The individual chapters within these sections are remarkably well-written and superbly edited. In general, these chapters are uniformly organized with an introduction, topical reviews, conclusions, and references. This volume is well-suited for reading as well as a reference text because the table of contents adequately describes the content on almost a page-by-page basis (with the backup and support of the subject index).

The first section includes a very impressive paper by Marc Schuckit reviewing his longitudinal research studies of children of alcoholics. The section overview and this first chapter set the tone for a well-organized, current, and very enjoyable scholarly reference. The remainder of the first section deals with issues relating to children of alcoholics such as neuropsychological factors, biochemical markers, neurophysiological factors, and genetics. It is not until the final section (pp. 287-344) that the most controversial aspects of the children of alcoholics movement are discussed.

Children of alcoholics represent a tremendously important

subject for clinicians. The children of alcoholics movement, like the self-help movement, the cocaine-is-dangerous movement, and other consumer-led medical revolutions, attempts to first bring to the attention of medical practitioners and researchers a concept that has been largely ignored. By identifying common characteristics and problems, the children of alcoholics have identified a syndrome and have challenged health professionals to study them and discover the consequences of living in an alcoholic family. They challenge all of us to help in the separation of nature and nurture by encouraging us to study children of alcoholics reared in nonalcoholic homes, adopted children of nonalcoholics in alcoholic homes, twins reared separately, and so on. Interestingly enough, we can see in this volume that clinicians are designing programs for prevention and education in the school and community and helping with treatment at the same time as the concept of children of alcoholics is being challenged by some.

It has been estimated that there are more than 20 million children of alcoholics over the age of 18 in the United States. Until very recently this fact has been ignored by medical researchers and clinicians. How children of alcoholics emerged as a consumer movement and did not evolve from Al-Anon or professional research or treatment is clearly described in the chapter by Brown. She shows us the emergence of the social movement of adult children of alcoholics, overnight with a clear identity, from beliefs and a body of literature based on personal accounts and clinical research. The movement is now more than 10 years old; the National Association of Children of Alcoholics was formed in 1983. Its proponents realize that academics question whether any generalizations about adult children of alcoholics can be made without prospective, or at least experimental, research. We psychiatrists are then perceived as reacting toward adult children of alcoholics the same way that "professionals" have reacted to Alcoholics Anonymous. Brown's chapter answers many questions that researchers and clinicians have about the adult children of alcoholics movement. The benefits of researchers and clinicians working together to do the necessary and important work of research and treatment evaluation are clear.

Dinwiddie and Reich jump right into the controversy on genetics and conclude that despite differences in research methodology most studies show the familial nature of alcoholism and that familial alcoholism is becoming more prevalent. The section on fetal alcohol syndrome is very well organized and comprehensive and could easily have been a book in itself. In five chapters this section provides the clinicians with nearly everything they need to know about this syndrome's medical and societal cost, neurobiology, clinical features, and prevention.

Similarly, the section on vulnerability to disease in the relatives of alcoholics and which diseases coexist with alcoholism is very useful. Of special interest for the researcher is the exhaustive chapter on vulnerability to cardiac disease, which has 318 references and six useful figures. This chapter is so well written that it is easy to understand cardiac effects even if you are not a cardiologist.

When compared with the remainder of the volume and the other sections, the section devoted to children of alcoholics provides information that has been available primarily through the general press. The authors are both comprehensive and critical of the methodology and conclusions of available studies and help us to organize what is really known, what is widely believed, and what programs are available in the schools and for treatment.

It would be difficult to imagine a finer academic reference

text on this subject. This book is surprisingly readable at the same time as it is encyclopedic in detail and organization.

CLINICAL PRACTICE

Current Treatments of Obsessive-Compulsive Disorder, edited by Michele Tortora Pato, M.D., and Joseph Zohar, M.D. Washington, D.C., American Psychiatric Press, 1991, 191 pp., \$28.50.

This brief and helpful book is a superb example of nonobessional writing and organization about obsessive-compulsive disorder and related disorders. It is aimed, unabashedly, toward the clinician, not the academic, so those seeking a review of the basic science aspects of obsessive-compulsive disorder should seek elsewhere. Those who want a comprehensive, concise, well-written review of the diagnosis and treatment of obsessive-compulsive disorder cannot do better than this volume.

Recognized experts address the important clinical questions about obsessive-compulsive disorder. The style, conciseness, and organization are remarkably similar among the authors, showing an exemplary job of editing. Chapters on drug treatment cover clomipramine, fluoxetine, fluvoxamine, and several augmenting agents. Evidence derived from anecdotal reports is clearly distinguished from that derived from controlled studies. Do not expect critical reviews of the studies. The approach is more a listing of their salient features. Readers who want to delve deeper can seek out the plentiful references to the original studies and more comprehensive reviews.

Psychotherapy of obsessive-compulsive disorder receives equal attention to drug treatment. There are chapters on behavior therapy, family therapy, and multifamily group therapy. Behavior therapy and drug treatment have the benefit of support from methodologically sound research. The other techniques do not. I wish the authors stressed this difference more, although a careful reader learns this. Similarly, the disparity between the evidence for the efficacy of behavior therapy of compulsions (strong) and obsessions (weak) might have been more emphasized.

Each chapter about a treatment approach not only reviews the literature but presents specific clinical guidelines and case histories. The style is so concise as to be almost telegraphic, and the advice is apodictic, making treatment appear more straightforward than it is.

For me, the most interesting chapter was the one by Greenberg and Witztum on the treatment of obsessive-compulsive disorder in strictly religious patients, a topic that cries out for a more complete discussion. There are two problems here: 1) differentiating obsessive-compulsive disorder from normative religious practices and 2) how to talk to the patient whose religious views differ from the clinician's. In the usual case, the clinician is less strictly religious than the patient. Greenberg and Witztum offer reasonable advice about this.

In the last chapter, Hollander, much too briefly, considers the intriguing issue of whether drugs useful in obsessive-compulsive disorder might work in related problems, such as body dysmorphic disorder (e.g., "I can't stop thinking about how ugly my nose is."), trichotillomania (there are data from a controlled study supporting clomipramine treatment), and depersonalization (less convincing to me). Given the empirical

basis of our knowledge of drug treatments in psychiatry (i.e., capitalizing on unexpected findings rather than fully understanding mechanisms), most of our knowledge comes from taking an effective treatment and extending it to other disorders (e.g., imipramine, made to be an antipsychotic, was tried in depression). Since so much psychopathology can be thought of as unwanted repetitions, we should energetically test serotonergic drugs in all these possibly related disorders. At present we cannot say what are the limits of this treatment.

I recommend this book highly.

ARTHUR RIFKIN, M.D.
New York, N.Y.

Post-Traumatic Stress Disorder: A Clinician's Guide, by Kirtland C. Peterson, Maurice F. Prout, and Robert A. Schwartz. New York, Plenum, 1991, 225 pp., \$34.50.

Having read a review of this work, the reader is likely to ask why this book was not published 10 years ago. Seldom do we see a book that so well fulfills a need. A large number of observations and opinions have been reported on posttraumatic stress disorder (PTSD) in the last 10–15 years in a mushrooming fashion, and we needed a synthesis and a balanced summary. The authors completed exactly this task, presenting an ordered, exceptionally well-organized, and penetrating study of the syndrome of PTSD.

After a brief introductory history, which in itself is a very stimulating chapter (I am sorry that it is so short), the authors discuss the subject in four main divisions. The first part describes the primary and secondary symptoms clearly with proper emphasis on the relative importance of the symptoms from gross manifestations to finely perceptible nuances. The syndrome in the area of pediatric psychopathology is not forgotten. Reading over this first part alone, mental health professionals should feel more confident and secure to make their own diagnostic formulations and assessments.

The second part deals with theoretical considerations from all major viewpoints. Reference is made to important comments by early psychoanalytical writers, and the reader is led through behavioral theories, cognitive and psychosocial models, cybernetics, and ecosystem models. Psychodynamic formulations are predominant, however. I assume that this was the most difficult part of the book to write, and the authors should be commended for the maturity of their overview, the good balance maintained among the various propositions, and the high level of intellectual penetration to the core of the different theories concerning etiology and mechanism of action.

The third section of the book deals with formal assessment, with reference to the mental status examination and alignment with *DSM-III-R*. The fitness (and failures) of traditional psychological tests are well discussed, and differential diagnosis occupies a large part of this section. Social and legal aspects did not escape the attention of the authors; malingering and embellished exploitation of the syndrome for monetary advantage are well described without partiality in either direction. The difficult patient and special problems that cannot be easily fitted into existing diagnostic frames are described with sophistication plus some good suggestions hinted at here and there. Comorbidity is an outstanding example of such difficulties. It occurs quite frequently in actual practice, and the authors warn the reader that a certain bias on the examiner's part is practically unavoidable. I personally feel that the problem of comorbidity should have occupied a larger part of the

discussion because of its clinical frequency, particularly with regard to the Vietnam veteran.

The fourth and last section of the book is, of course, about therapy. Again, as in the preceding chapters, thoroughness is the outstanding virtue. The section is sufficient in details to teach or even to train clinicians to improve their therapeutic skills.

Modestly, the authors gave the subtitle of "A Clinician's Guide" to the book. This is correct, but the book is much more than this. It is a concise textbook. It is written without verbosity, yet it is not dry reading, always staying within the limits of the essentials. In spite of the fact that it is written by three different authors, the book has uniformity and fluency in its style. It is a most enjoyable reading. In the certainty that within a reasonable time a second edition will be forthcoming, I respectfully suggest that more attention be paid to the sexually and physically abused child. Child abuse is a subject, like PTSD itself, that is still under ongoing exploration. The abused child who responds with behavioral disaster to his or her abuse is often diagnosed as having conduct disorder instead of PTSD. I hope that the authors agree with this and give a little more space to the abused child in their second edition.

In summary, this book is wonderfully written in a most enjoyable, fluent style, bringing order and clarity to the subject of PTSD. It gives a great deal of useful hints to the practicing clinician and the academically oriented reader as well.

LASZLO VARGA, M.D., PH.D.
Martinez, Calif.

Memory Disorders: Research and Clinical Practice, edited by Takehiko Yanagihara and Ronald C. Petersen. New York, Marcel Dekker, 1991, 503 pp., \$125.00.

As this book demonstrates, our usual ways of conceptualizing and assessing memory in clinical practice are outdated. Repeating a series of numbers forwards and backwards, recalling three words, describing what one ate for breakfast, and divulging one's birth date are supposed to assess immediate, short-term, recent, and long-term memory. But this division of memory is antiquated and in any case not assessed by the evaluation. If one always eats the same thing for breakfast is this a test of recent memory? Does one really remember when he or she was born? The model behind this viewpoint saw the brain as analogous to a pre-electronic office, with information flowing from desk to filing cabinets to back office to microfiche. Current views are more closely tied to neuroanatomy, not neurofantasy, and link different neuroanatomical structures with different memory functions. These functions include declarative or explicit memory (the only one tested by our current clinical examination) as well as procedural or implicit memory.

Declarative memory is that which one is aware of knowing. It can be divided into semantic memory for information that is not contextually bound (i.e., knowing your birth date) and episodic or autobiographical memory, actual recollections of yesterday's contextually bound memory. Implicit memory comprises a series of functions that one may not be aware of knowing, such as motor skill learning, procedural problem solving (i.e., doing the Tower of Hanoi problem), and different forms of priming (i.e., being able to recognize a word or shape more easily after previous exposure). Since these functions are subserved by different anatomical structures, individuals with disorders of declarative memory, which usually involve the hippocampus (e.g., Alzheimer's disease) or the dorsomedial

thalamic nucleus (e.g., Korsakoff's syndrome), may have intact implicit memory. For example, since the basal ganglia of amnesic individuals are intact they can acquire motor skill such as mirror writing without being aware that they have done so.

The first section of this book provides an excellent overview of these new models of memory function, their neuroanatomical and biochemical substrate, and the effect of drugs on these functions. Building on this information, the next section reviews methods to evaluate memory, including some simple clinical procedures such as the "three words and three shapes" test, which is a good candidate to replace much of our current memory assessment. The third section deals with memory dysfunction in neuropsychiatric disorders. Although informative, many of the clinical chapters do not make enough reference to the models presented earlier in the book. The primary reason for this is that a sufficient body of knowledge does not yet exist to accurately describe the full range of memory deficits and retained functions in many of the disorders. A striking exception to this is Craick's chapter on memory function in aging, which provides interesting findings on differential effects of normal aging on different types of memory, including declarative versus implicit memory. The final chapter deals with treatment and is less clinically useful than offering hints of future treatments.

DANIEL J. LUCHINS, M.D.
Chicago, Ill.

PSYCHOPATHOLOGY

Cognitive Bases of Mental Disorders: Annual Review of Psychopathology, vol. 1, edited by Peter A. Magaro. Newbury Park, Calif., Sage Publications, 1990, 307 pp., \$39.95; \$19.95 (paper).

This book launches a new annual review series, the first devoted to psychopathology. Each volume of the series will critically explore research into a specific element of psychopathology as it is expressed within conventional diagnostic groupings. Thus, this maiden volume is focused on cognition as it presents in obsessional illness, mania, antisocial personality, and so on. Later volumes will similarly treat such topics as personality, neurology, and social behavior.

This organizational strategy is a critical choice, and it is problematic. The editors argue that psychopathological signs and symptoms are not unique to specific diagnoses, that depression, for example, may appear with any of them. True enough. Psychopathological diagnoses are syndromes delimited by a mix of pathological signs and symptoms. Often one manifestation is necessarily present while many others may or may not be present. Depressed mood is a necessary feature of major depression, whereas it is often but not always present in obsessive-compulsive disorder. Sometimes, a specific sign cannot be accommodated within a syndrome; for example, delusions within panic disorder. Having accepted and worked with this basic logic for several decades, I found that focusing on only one psychopathological feature, in this instance cognition, is vexing and artificial without apparent compensating advantages. How is one to evaluate studies of cognition in depressed or manic persons without reference to mood or to associated phenomena such as diurnal variation? What do studies of memory in schizophrenia tell us if we do not simultaneously consider anxiety? The restricted perspective also

seems to undermine thinking about etiology. How can one formulate etiologic hypotheses concerning a defect in cognition that might be found across diverse diagnostic categories? Perhaps this is why "genetics" does not appear in the index and I found only passing mention of it in the text.

This book made me realize that there is little consensus about what is denoted by "psychopathology." Cognitive dysfunction in schizophrenia is defined by one author as "bizarre incoherence, inadequate or incomprehensible ideas." Can this mean that we ignore delusions when discussing cognition in schizophrenia? And indeed, delusions get no attention in that chapter and little anywhere else in this book. How are we to understand such an omission in a book that purports to deal with cognition in psychopathology?

Other problems with definition are illustrated in the long chapter (61 pages with 306 references) on "histrionic/over-conventional personality," a designation that appears more or less to fit with what was once called "grand hysteria." However, the criteria marshaled to delimit the entity are based on constructs such as "cognitive processing style" and "reflectivity-impulsivity personality style." Such psychometric abstractions are difficult to grasp, but, more fundamentally, what evidence links them to psychopathology? Where on the continuum of "reflectivity-impulsivity" is pathological, and what evidence establishes the implied association with disorder? What is the population base rate of pathological scores and what are the age- and sex-specific frequencies? What are the rates of type 1 and type 2 errors of classification? Such questions, the traditional meat of pathology, are not addressed.

A niche is surely available for the projected series of annual reviews of psychopathology. I hope it becomes a smashing success. However, I think that this volume is an unfortunate start. Psychiatrists will find little help with their diagnostic problems, and their insights into pathogenic mechanisms will be muddled, not strengthened.

LEONARD L. HESTON, M.D.
Minneapolis, Minn.

Person Schemas and Maladaptive Interpersonal Patterns, edited by Mardi J. Horowitz. Chicago, University of Chicago Press, 1991, 433 pp., \$34.95.

"Person schemas" are concepts in theories of psychology. They refer to mental structures of meaning that integrate knowledge about self and others, organize thoughts, feelings, and actions, and may operate consciously or unconsciously—which is to say they refer to just about everything that might interest a psychodynamically oriented clinician. Of course, there are other concepts in other psychological theories that refer to the same domain. Person schemas exist in the minds of psychological theorists just as these other concepts do. For the clinician, researcher, or student who is not irreversibly committed to one or another theory and its related concepts, the critical question is which are best or at least most useful for some purpose. Which concepts organize the data, suggest new questions, can be related to quantifiable, operationalizable, and reliable measures and instruments, generate interesting, testable, and falsifiable hypotheses, lead to creative and potentially therapeutic insights, suggest linkages to related fields of inquiry, have an aesthetic or intuitive elegance, and in general fulfill the criteria by which we evaluate concepts and theories in psychology?

This volume, the third from the Program on Conscious and Unconscious Process sponsored by the MacArthur Foundation, is edited by Mardi J. Horowitz, who directs the program. Dr. Horowitz writes or co-authors the introduction and six of the 17 chapters. I know of no work that explores the concept of person schemas more carefully and systematically, nor of any group more qualified to do so. The book consists of a collection of independent papers by experts who are at the cutting edge of an emerging interdisciplinary field. The papers vary in focus from detailed descriptions of how a specific instrument is employed to general discussions of the relationship between psychodynamic and cognitive models.

The volume is divided into four parts. The first explores the concept and the theory. The second introduces three specific methods, Horowitz' role-relationship models configuration, Lester Luborsky's core conflictual relationship theme, and Lorna Benjamin's structural analysis of social behavior (presented by Dianna Hartley). These methods are both described and applied to two case summaries, each of a professional man in his mid-30s with a "compulsive" personality who had been treated in Dr. Horowitz' clinic. The third part of the book compares the three methods, and the final part introduces a discussion of information processing models as potential schemas linking psychodynamic, cognitive, and neurobehavioral theories.

Each of the three methods that are discussed, explored, compared, and contrasted in the major part of the book is a strategy for reducing data and simplifying, codifying, and organizing clinical material as a step toward systematic research. The subject matter of the book focuses on the methods and the theories that generated those methods, not the psychological data or the investigation of behavior that these methods might allow. The discussion, therefore, will interest methodologists and researchers far more than clinicians or theorists. The ultimate test of any method is that it accomplishes some useful goal, but we are not yet up to that point; here we are only asking whether the method can be used at all and how it might compare with other methods. The casual reader will find condensed, systematic, and organized psychodynamic formulations that seem, as one might expect, somewhat abstract and formulaic and that contain few surprises. These studies demonstrate that these methods can be used; the next step—the new discoveries that might result from employing them—should be the exciting one.

The final section of the book is the most speculative. It discusses the relationship between psychodynamic theory and models derived from information processing, including an interesting discussion of the difference in the demands placed on such models by "simple" cognition or perception compared with the "quite novel combinations of conflicting, ambivalent or ambiguous conscious and unconscious thoughts, affects, expectations, drives and wishes about multiple people or events" (p. 341) implicit in psychodynamic theory.

Horowitz says, "Building a bridge between psychodynamic and cognitive science is possible, but it involves evolutionary change in both theories" (p. 413). He might have added that it is not yet clear what value such a bridge will have, how and whether it will enrich both theories, and whether the time is ripe to begin. He concludes by saying, "If that bridge can be built, it could lead to a much improved understanding of the cause and prevention of personality disorders, the enriched development of character, and the integration of the psychotherapies" (p. 423). This is the vision that drives the entire

project. Judging on the basis of the work discussed here, I think it remains an appealing but as yet unrealized potential.

MELANIE KLEIN

Melanie Klein, vol. II: *The Ego and the Good Object, 1932–1960*, by Jean-Michel Petot; translated from the French by Christine Trollope. Madison, Conn., International Universities Press, 1991, 282 pp., \$40.00.

Melanie Klein, perhaps the most original of the early psychoanalysts after Freud, never achieved in the United States the importance she attained in Great Britain. One of the first child psychoanalysts, Mrs. Klein believed that "anxieties of a psychotic nature are in some measure part of normal infantile development," and she posited a crucial depressive position in the first year of life that was more than a stage; it was a basic structure of personality. Many American psychoanalysts dismissed her ideas because they seemed incompatible with what was known about cognitive and affective development in children. Mrs. Klein and Anna Freud were leaders of conflicting schools in England, but Anna Freud's ego psychology seemed to build a better bridge between academic psychology and psychoanalysis, and for this and for other reasons it dominated the scene in the United States. However, out of Klein's work would come object relations theory, a psychodynamic perspective that proved crucial to many psychotherapists. This was particularly the case for psychotherapists who attempted to treat psychotic and borderline patients.

As is now well recognized, Sigmund Freud's structural theory deconstructed the subjective sense of self and therefore sidetracked the possibility of a psychoanalytic conception of this crucial aspect of consciousness. Arguably, every important neo-Freudian from Sullivan to Horney to Erikson to Kohut to Lacan has had the task of reconstructing a phenomenologically meaningful psychoanalytic theory of the self. Klein's theory of object relations was the beginning of that enterprise. Feminists have now recognized Klein's importance as a theoretician and as a leading force in psychoanalysis.

Mrs. Klein's theorizing met opposition not just because she disagreed with Anna Freud and because her ideas seemed contrary to what was known about child development. As one of the first psychoanalysts to do play therapy, she imagined her way into the meaning of the play in interpretive narratives that seem to go far beyond her observations. Her paper "The Importance of Symbol Formation in the Development of the Ego" (1) is a classic both for its clinical brilliance and its overreaching. Mrs. Klein invented the concept of projective identification, and in her description of symbol formation in the child she seems at times to be using that mechanism. Despite her theoretical extravagances, Mrs. Klein opened a window into the aggressive and violent fantasies of the child, the good and the bad object, splitting, the transition from anxiety to obsession, the importance of envy, and other preoccupying emotional states of the young child.

Child psychiatrists who ignore Melanie Klein's writings deprive themselves of a unique insight into the anxious child's subjective experience. If Sigmund Freud's work tore the veil of repression from infantile sexuality, Mrs. Klein exposed the violent passions and the related terrors of that supposed age of happy innocence.

Petot's volume, the second he has devoted to Mrs. Klein, deals with her writings during the years she was elaborating her theories and establishing the "Kleinian school" in England. Mrs. Klein's "discovery of the depressive position in 1934" launched this period of theory building. Petot writes in French, but the translation by Christine Trollope captures Petot's underlying thesis. He insists that Mrs. Klein has actually *discovered* something which is really there and that her work has both "heuristic value and objective validity." He claims that Klein's theories are fully compatible with those of Piaget and what is known empirically about child development. The study of infants has certainly pushed back the frontiers of psychological development, but whether Klein's speculations can be confirmed is another matter. For example, as Petot recognizes, many American psychoanalysts have found in the "separation" experience enough to make Klein's theories superfluous. Furthermore, "separation" and its effects can be studied in other species. The depressive position, with its symbols, splitting, mechanism, etc., may be compatible with empirical data but may not be confirmable except at the level of human empathy.

Petot's book is written with the painstaking precision of a philosopher, with the clinical understanding of a psychoanalyst, and with the empirical perspective of a developmental psychologist. Trained in all these disciplines, Petot has brought them together in this exegesis of Mrs. Klein's theories. Many psychoanalysts have attempted to explain Melanie Klein or to offer their own versions of her work. None has produced a clearer exposition. Even Mrs. Klein might agree that of all her students, Petot has the clearest sense of her ideas. Unfortunately, his impeccable scholarship will be impenetrable to those who do not already "speak" Kleinian. For those who still need an introduction to Mrs. Klein's work, the collection assembled by Juliet Mitchell (1) is the place to go before you try to wade through the deep going of Petot's very important contribution to Klein scholarship.

SELF PSYCHOLOGY

Progress in Self Psychology, vol. 6: The Realities of Transference, edited by Arnold Goldberg. Hillsdale, N.J., Analytic Press, 1990, 263 pp., \$32.50.

Such diverse subjects as empathy, the working through of "selfobject" transferences, selfobjects of the second half of life, the origins of ambition, addictive personalities, AIDS patients, Vincent van Gogh, and the application of evolutionary biology to psychoanalysis are examined in this volume. What is the unifying thread? Kohut clearly hoped that his self psychology would advance a new humanism in psychoanalysis and expand into a general psychology. The editor of this book, the sixth volume in a series devoted to progress in self psychology, strives for that goal by inviting contributors to broaden the perspective of self psychology by applying it to the arts, biology, and the somatopsychic conditions.

The book is divided into four major sections: Progress in

the Theory of Self Psychology, Progress in Development, Progress in the Approach to Psychopathology, and Progress in the Application of Self Psychology. The first section consists of half of the 14 papers in the book and deals with the evolving theory of self psychology. Here, Stolorow discusses Lichtenberg's paper "Rethinking the Scope of the Patient's Transference and the Therapists' Counterresponsiveness" and Leider's "Transference: Truth and Consequences," and Lachmann comments on Anna Ornstein's "Selfobject Transferences and the Process of Working Through." Such an arrangement provides for continuity and perspective in the section. The articles under discussion are well-written and offer interesting perspectives. The reader gets the flavor of participating in a 1-day workshop of the local psychoanalytic society, complete with a discussion of the papers. Basch and Meares round out the section on theory by sharing their thoughts on empathic understanding and the role of material objects in the development of the self, respectively.

The section on progress in development is disappointingly brief—only one paper by Galatzer-Levy and Cohler, who write about selfobjects in the second half of life. It maintains the growing emphasis on viewing development as a continuous life process with epochs and critical events. This chapter is clinically refreshing and lucid while weaving in the tenets of self psychology in a convincing manner.

The three papers in the section on progress in the approach to psychopathology deal with popular and relevant subjects: the ambitions of women, addictions, and the psychodynamic consequences of AIDS. Leib presents a very readable, current self psychology perspective of the struggles women face in their ambitions related to motherhood and family, work, and making an impact on their environment. Cohen and Abramowitz share their experience and understanding gained from

working with AIDS patients. They give a highly informative and sensitive account of the devastating impact of AIDS on the self and suggest helpful therapeutic approaches.

In the final section on progress in the application of self psychology, the three papers examine the therapist as muse, identify and expand on selfobject factors in Vincent van Gogh's creativity, and suggest clues from evolutionary biology to help explain the resistance to self psychology. Of the three papers I found Baker's "Vincent van Gogh: Selfobject Factors in Motivating, Facilitating, and Inhibiting Creativity" the most intriguing. Baker has researched his subject well and draws on his impressive knowledge of art and culture as well as psychoanalysis to offer the reader an attention capturing and plausible narrative of the significant object relationships in Vincent van Gogh's tortured existence and their impact on his creativity.

Does *The Realities of Transference* meet Kohut's exacting standards and satisfy his vision of extending the psychology of the self to a general psychology? The objectives for the papers were attained insofar as they embrace a wide scope of topics and persistently interpret the phenomena from the self psychology perspective. Among the potpourri of papers there was some variation in the academic depth and organization, and perhaps the reader will be drawn more to one section than another. Most annoying was the surprisingly poor copy editing; spelling errors abounded, sentences were printed twice, and syntax was violated. Overall, however, both novitiates and early devotees of self psychology are certain to find several chapters of interest that illuminate the ongoing progress in self psychology.

Letters to the Editor

Recovery From Protracted Depression in Old Age

SIR: Recovery from very long episodes of depression has been described in younger (1, 2) but not older patients. Thus, I report the case of an 80-year-old man who recovered from a depressive episode lasting 7 years.

Mr. A was a 74-year-old businessman who presented with a 1-year history of depression, anxiety, decreased concentration, anorexia, initial and middle insomnia, anhedonia, and loss of interest in and withdrawal from previous activities. There was no past personal history of affective disorder, although he drank 6 ounces of scotch per day most of his adult life. His physical health and cognitive function were excellent.

With encouragement, Mr. A stopped drinking. Despite receiving antidepressant medication and a course of ECT he remained depressed for 6 more years. Antidepressant medication included successive trials of imipramine, trimipramine, nortriptyline, trazadone, and phenelzine, alone or in combination with lithium carbonate, at maximum tolerated doses, for 4 to 6 months. Finally, 7 years after he first became ill, Mr. A recovered completely. Three years later, at age 83, he continued to enjoy life to the fullest and resumed all of his activities.

It is possible that the patient's recovery was related to antidepressant treatment but more likely that it was related to the natural course of his illness. In either case, the persistence of treatment was important to the patient in coping with the hopelessness induced by his prolonged illness.

Follow-up studies of younger patients with protracted depression have reported rates of recovery from this condition and prognostic factors (3, 4). Similar studies of older patients are needed. In the meantime, this case report provides some hope to therapists, patients, and their families, that recovery in old age may come even after very long periods of illness.

Use of Cocaine to Prevent Opiate Withdrawal

SIR: We have previously reported that cocaine-dependent opiate addicts have less severe naloxone-precipitated withdrawal

than opiate addicts not dependent on cocaine (1) and that, in morphine-dependent rats, acute pretreatment with cocaine attenuates the severity of naloxone-precipitated withdrawal (2). However, the purposeful use of cocaine to prevent opiate withdrawal has not been previously described. The following patient reported using cocaine to minimize his opiate withdrawal symptoms.

Mr. A, a 32-year-old man dually addicted to cocaine and heroin, was admitted to the inpatient unit for a research protocol, during which he would be administered cocaine. He reported preferentially injecting the combination of a \$20 bag of heroin with a \$5 dollar bag of cocaine. He claimed that he added the cocaine, on the advice of his dealer, because cocaine postponed his opiate withdrawal symptoms (rhinorrhea and stomach cramps) for 1 hour or longer.

Mr. A claimed only minor subjective effects from a \$5 bag of cocaine. He claimed that he did not like using higher doses of cocaine or using cocaine alone. He was administered cocaine, 2 mg/kg intranasally, in combination with methadone, as part of a research protocol. He reported that this higher cocaine dose was anxiogenic and generally unpleasant. At the end of the protocol, Mr. A was referred to methadone maintenance. He reported that he had not used cocaine during his first 4 months on methadone maintenance.

Mr. A's cocaine use stopped when his opiate dependence was treated. A subset of addicts who use low amounts of cocaine cease cocaine use after entering methadone treatment (3). This patient's "prophylactic" use of low doses of cocaine distinguished him from the majority of dually addicted patients we have interviewed. Most dually addicted patients report having experienced opiate withdrawal after cocaine use and report no relief of opiate withdrawal by using cocaine (submitted abstract of S. Stine and S. Satel). Although an addict's claim that he uses cocaine to treat opiate withdrawal may not reflect a true cause-and-effect relationship, it is relevant information for designing a treatment plan.

Oral Versus Intravenous Caffeine Augmentation of ECT

SIR: R.J. Ancill, M.D., and W. Carlyle, M.D. (1), recently reported the use of oral caffeine for augmentation of seizures during ECT when intravenous sodium caffeine benzoate is unavailable. They used doses of 300 to 1000 mg, 1 hour before treatment and reported that geriatric patients responded with longer seizures without increased anxiety or adverse hemodynamic effects.

Several augmentation techniques have now been described for eliciting adequate seizures in patients who develop a high seizure threshold during a course of ECT. These include the use of intravenous caffeine (2) and the use of oral theophylline (3). While oral caffeine may be an adequate substitute when the intravenous preparation is unavailable, we believe that the intravenous route is probably preferable. Intravenous caffeine administration allows titration to the minimal effective dose for each treatment. We initiate intravenous caffeine at the ECT session when we are first presented with an inadequate seizure at maximal stimulation. If an adequate seizure is not elicited, caffeine can be added intravenously while anesthesia is continued. We then restimulate the patient 5 minutes after administration of the caffeine. Such intervention would not be possible with the oral technique described by Drs. Ancill and Carlyle. The rationale for utilizing the smallest possible dose relates to the potential hemodynamic and dysrhythmogenic complications of caffeine treatment described, respectively, by Acevedo and Smith (4) and by us (5). Like Kellner and Batterson (6) we find that dosages lower than those originally recommended can prolong seizure length. A one-half ampule of sodium caffeine benzoate (125 mg active caffeine) is often effective. Given the slow elimination of caffeine, with a half life of 140–270 minutes after intravenous infusion (4), and a (presumably) longer effect after oral intake, the use of the most rapid intervention would be superior in geriatric or medically compromised patients.

RICHARD JAFFE, M.D.
WILLIAM R. DUBIN, M.D.
Philadelphia, Pa.

Dr. Ancill and Dr. Carlyle Reply

SIR: We welcome the comments of Dr. Jaffe and Dr. Dubin concerning oral versus intravenous caffeine augmentation of ECT. We certainly support the use of augmentation techniques, especially in patients who have developed a high seizure threshold or for whom the standard settings produce an unacceptable level of confusion. As we pointed out in our original letter, the option of using an intravenous regime is

not available to us and we wished to share our experience with the oral preparation of caffeine in order to advise our colleagues of this possibility.

Whether or not, as Drs. Jaffe and Dubin point out, intravenous caffeine does have advantages should be determined by controlled studies. However, we can confirm that with our increasing clinical experience we can report no significant side effects from utilizing the oral route.

Of particular interest to us is not only the ability to reduce the seizure threshold in patients who fail to have an adequate seizure but also to reduce the side effects, especially confusion, in geriatric patients with cognitive impairment who have significant depressive syndromes that will respond to ECT.

Retinopathy and Bright Light Therapy

SIR: Dr. Wendy Vanselow and colleagues (1) raise the concern that light therapy of 2000 lux may damage the retina in susceptible human eyes and exacerbate existing retinopathy. They recommended mandatory ophthalmological screening of all patients with seasonal affective disorder.

We believe that their concerns and recommendations are unwarranted for the following reasons.

First, even in the case of the patient with serious retinopathy described by Dr. Vanselow and colleagues, suggestions that light therapy would be deleterious are purely speculative. Although staring directly into the sun (with a luminance of approximately 1.7×10^5 cd/cm²) can induce serious retinopathy (2, pp. 43–68), there is no evidence that such retinopathy can be induced by the levels of light used in light therapy (0.7 cd/cm²). Even in the condition where the potential for bright skylight (100,000 lux or 3 cd/cm²) damage to the retina has been most widely discussed, namely age-related macular degeneration, this putative causal relationship remains highly controversial (2, pp. 89–124).

Second, light therapy levels, even at 10,000 lux, are not very bright compared to bright skylight (approximately 100,000 lux). Light therapy at 2000 lux is comparable to looking at the sky during sunsets and sunrises. Although rodent retinal photoreceptors can be damaged at intensities much less than 2000 lux (2, pp. 69–88), in primates such damage has been demonstrated only at 10,800 lux with the eye dilated for 12 hours of continuous exposure (3). Exposing a monkey's undilated eye at this intensity 12 hours per day for 4 weeks does not produce photoreceptor damage (4). We have estimated that, in a worst-case analysis, over 6,400 half-hour sessions of light therapy at 10,800 lux (0.7 cd/cm²) would be required to induce threshold photoreceptor damage in the human retina. That is equivalent to approximately 73 winters of daily light therapy (M. Waxler et al., unpublished manuscript).

Third, there is no evidence that ophthalmological examination can detect prior light-induced photoreceptor damage. Thus, there is almost no benefit to be gained from ophthalmological screening in all cases. Furthermore, the extremely bright light of the ophthalmoscope (200 cd/cm²) has the potential for phototoxic effects in lengthy ophthalmological examinations and has itself been a focus of concern (5).

Although there is no evidence that light therapy exacerbates human retinopathy, there is some theoretical concern. Therefore, we recommend taking a careful ophthalmological history and consulting with an ophthalmologist or optometrist

if deemed necessary. To err on the side of caution, we would recommend not administering light therapy to patients with aphakic eyes and those with actively degenerating retinal disorders, such as diabetic retinopathy, retinitis pigmentosa, and age-related macular degeneration. In addition, we recommend excluding patients who are being treated with hematoporphyrin or similar highly light-sensitive compounds.

We have previously commented on the potentially harmful effects to the eye of light sources containing UV light (6) and recommend screening out UV rays during light therapy unless UV rays are found to be important for an antidepressant effect, an unresolved issue at present.

Dr. Vanselow and Associates Reply

SIR: In dismissing the advisability of pretreatment eye checks for light therapy, Dr. Waxler and colleagues fail to address two important matters raised in our initial letter.

First, considerable variability in susceptibility to retinal phototoxicity is described, and particularly light-induced damage may exist in already diseased or damaged retinas (1). Recent reports implicate ambient light exposure as contributing to the process of age-related macular degeneration (2), and the morphology of that condition closely resembled the changes in our patient's left eye.

Second, considerable medicolegal importance may be given to the detection of preexisting retinal lesions in patients about to undergo treatment that is arguably retinotoxic.

The comment by Dr. Waxler and colleagues that "almost no benefit is to be gained from ophthalmological screening in all cases" is contradictory to their own recommendation to take "a careful ophthalmological history and consulting with an ophthalmologist . . . if deemed necessary." Experience has shown that many patients are unaware of preexisting eye damage, as was illustrated by our case history.

In view of the relative ease of obtaining a pretreatment ophthalmological examination it would seem foolhardy to omit

one when this could be considered essential to informed consent.

Furthermore, by undergoing a comprehensive eye check there may be the added benefit of reinforcing the need to adhere to strict guidelines for use of the light box. It is not difficult to imagine how a therapy that is increasingly available for use in the home without direct supervision could be misused by the person not only for whom it was intended but by other household members.

We would, therefore, conclude that a minimum standard of care for recipients of phototherapy should include ophthalmological screening and surveillance.

Comorbidity of Personality Disorders

SIR: The recent article on patterns of comorbidity of personality disorders by John M. Oldham, M.D., and associates (1), exemplifies the arduous work needed if we are to better understand their fundamental features. As have others, the investigators found that patients often met criteria for more than one personality disorder, leading to the suggestion that a two-level system be used on axis II. Patients meeting criteria for two or fewer disorders might be viewed as having a "focal" personality disorder, while those with more than two disorders would receive a diagnosis of "extensive" personality disorder, including a description of the predominant characteristics present. While this suggestion has merit, we are concerned that the term extensive could be taken to mean that the patient has a more severe condition, or one with a poorer prognosis, than does one with a "focal" disorder, as is implied when one speaks of focal versus extensive lesions in medicine. This may not be the case, as a patient with one or two disorders may show impairment as severe as one with several disorders. A less potentially pejorative term, such as diverse personality disorder, might better describe those cases wherein patients meet criteria for three or more disorders. Clearly the high degree of overlap among categories and the modest agreement between the two interviews used indicates the need for further research in this area.

MICHAEL O'BOYLE, M.D., PH.D.
CHARLES E. HOLZER, PH.D.
Galveston, Tex.

Dr. Oldham and Dr. Skodol Reply

SIR: We received the letter from Dr. O'Boyle and Dr. Holzer and appreciate their recognition of the complexity of comorbidity studies of personality disorders. They express concern regarding our suggestion to adopt a convention that a patient with three or more personality disorders be diagnosed as having "extensive personality disorder," followed by a list of characteristics using *DSM-III-R* diagnostic terms. Their concern that "extensive" might erroneously imply a measure of severity is well taken. Certainly, there are patients with selected single personality disorder diagnoses or with only two who are more ill than patients with three or more less disabling diagnoses. In our experience, however, numbers of personality disorder diagnoses in a given patient are frequently correlated with severity of psychopathology and impairment in functioning. An alternative word, such as "diverse," would accomplish our purpose and would be entirely acceptable. Still needed are studies that address the applicability of a hierarchy among the personality disorders for cases meeting criteria for multiple disorders. Nonetheless, we are grateful to Drs. O'Boyle and Holzer for their suggestion.

New York, N.Y.

Obesity and Multiple Personality Disorder

SIR: Donald W. Black, M.D., and associates (1) sought to determine the association between mental disorder and morbid obesity in 88 bariatric clinic patients. They reported an empiric correlation between morbid obesity and anxiety disorders (most prominently posttraumatic stress disorder [PTSD]), mood disorders, bulimia, and tobacco dependence but did not screen for dissociative disorders.

Once thought to be extremely rare, the dissociative disorders have recently come to be seen as a major category of psychopathology affecting up to 10% of the population (2). The patient sample reported by Dr. Black and associates may have been at even higher risk for dissociative disorders because they were predominantly female (3), had low socioeconomic status, and had high rates of PTSD and eating disorders (4).

Surgical treatment of obesity in a patient with multiple personality disorder might be contraindicated if it were found that the obesity was the result of the covert actions of one "personality." A screen for dissociative disorders would be very helpful to those doing treatment planning and could be accomplished using such measures as the Dissociative Experiences Scale and the Dissociative Disorder Interview Schedule (5).

HOWARD WETSMAN, M.D.
New Orleans, La.

SIR: Morbid obesity is associated with significant emotional distress. Dr. Black and colleagues demonstrated this finding in the preoperative assessment of gastric stapling patients, noting high lifetime rates for mood disorder, anxiety disorder, bulimia, and personality disorder. However, caution should be exercised in inferring specific psychopathology in the morbidly obese, and the authors rightly point to the need for longitudinal study to assess fully the psychosocial outcome of vertical banded gastroplasty.

We conducted a prospective evaluation of gastric stapling patients (1) with similar sample characteristics (age, sex, race, socioeconomic status) using comprehensive assessment measures of clinical interview, *DSM-III* axis I and II diagnoses, locus of control, eating disorder profile, and measures of lifestyle, sexual function, and interpersonal relationship. Patients were examined preoperatively and postoperatively after a mean period of 13.6 months at which point the mean loss of weight was 46.4 kg. At baseline, measures of anxiety, dysthymia, and somatic concern were noted to be high. However, a significant reduction was noted in the postsurgical period. In addition, many aspects of personality showed some change, with reduction of schizoid, avoidant, and passive aggressive traits and, to a lesser degree, some increase in histrionic and narcissistic characteristics. Improvement in interpersonal relationships, sexual function, socialization, and self-perception was noted. The Eating Disorder Inventory (2) demonstrated the large measure of body dissatisfaction in the morbidly obese even exceeding the levels known for anorexia nervosa. Significant improvement was noted after surgery. Of importance was the absence of major psychiatric illness in patients before or after surgery. In general, these findings compliment our previous study of gastric surgery patients (3).

Although distress was prominent in the morbidly obese, in contrast to Dr. Black and associates, we did not find psychiatric illness. Moreover, even axis II pathology or personality disorder assessed by the Millon Clinical Multiaxial Inventory (4) was not prominent. However, change in personality profiles was noted postsurgically, suggesting a state-dependent rather than trait condition linked to morbid obesity. Obviously the differences in the various studies may depend to some extent on methodological issues such as the type of instrument used to measure psychiatric illness, covariation between disorders, etc. However, in light of our data, specific psychopathology—particularly personality disorder—attributed to the morbidly obese remains unproven.

It will be interesting to see the results from Dr. Black and colleagues of the patients after gastroplasty, both to assess outcome and elucidate relevant psychiatric variables. In future studies it will be important to broaden outcome measures to include general physical health and quality of life.

Dr. Black Replies

SIR: Dr. Wetsman has made several interesting and useful comments about the prevalence of dissociative disorders in morbid obesity. The Diagnostic Interview Schedule (DIS) does not include dissociative disorders and to screen for this would require using another instrument, such as one of those that he recommends. As he notes, preliminary data suggest that morbidly obese subjects are prone to developing dissociative disorders. I doubt that dissociative disorders are as prevalent as Dr. Wetsman believes, but I look forward to seeing additional data on this group of patients to confirm or refute these associations.

I thank Drs. Chandarana and Conlon for bringing their work to our attention. In their study of gastroplasty patients, they failed to find psychiatric illness and noted that "even axis II pathology or personality disorder" was not prominent. Despite our data and that of others, they believe the association of psychiatric illness and morbid obesity remains unproven. We beg to differ. As noted in our article, a comprehensive survey of the literature published since 1960 pertaining to psychiatric diagnosis in morbidly obese subjects shows a strong link between morbid obesity and various mental illnesses, particularly depression and personality disorders.

Our study is one of the first to use structured interviews to assess both axis I and axis II disorders in morbidly obese persons and to provide a comparison group. Unless one dismisses outright the value of these assessments (the DIS and the Structured Interview for DSM-III Personality Disorder), both adequately studied for reliability and validity, one must assume that the findings have value. In fact, morbidly obese persons have substantial axis I and axis II pathology that should be taken into account by their caregivers. I suspect that the findings of Drs. Chandarana and Conlon differ from ours because they did not use structured interviews but relied on self-report instruments not designed to generate diagnoses. We, too, have data from self-report instruments that we will publish in the future, along with data collected 6 months and 1 year after gastroplasty to test the association between psychopathology assessed at intake and weight loss in follow-up.

Caloric Requirements for Weight Maintenance: A British Viewpoint

SIR: While agreeing with Theodore E. Weltzin, M.D., and associates (1), that "elevated caloric requirements . . . may particularly contribute to relapse in anorexic patients," I am disquieted to read that physical activity has not been included as an independent variable.

Many of the anorexic patients admitted to our eating disorders unit use exercise as a method of weight control in addition to dietary restriction. In the experimental condition de-

scribed by Dr. Weltzin and colleagues, where food intake is measured with such accuracy, an increase in exercise by an anorexic patient could be anticipated. Discharge from the restriction of a hospital environment may also precipitate an increase in physical activity in an anorexic patient. A long-term, weight-stable anorexic woman is less likely to exhibit the compulsion to increase her activity level.

The variation in physical activity is accounted for in the estimated energy requirements in the United Kingdom (2). The formula applied is that the daily energy expenditure is a multiple of the basal metabolic rate and the physical activity level. For example, the estimated energy requirement for an inactive, 55 kg, 20-year-old woman is 7.6 MJ/day (1828 kcal/day) and for a very active, but otherwise similar subject 12 MJ/day (2887 kcal/day): a discrepancy of 1059 kcal/day. Hence the contention that exercise must be considered when estimating caloric requirements.

A second point of interest is that the recommended weight table in the United Kingdom is that recommended by Passmore and Eastwood (3, pp. 44, 55, 518, 521). When Metropolitan Life Insurance Co. tables (4) are quoted (5) they are listed as the 1983 version, not the 1959 version as described in the article by Dr. Weltzin and colleagues.

It would be interesting to know the rationale for excluding physical exercise from the calculation for caloric requirement and why weight tables that in the United Kingdom are considered outmoded were used.

Dr. Weltzin and Associates Reply

SIR: We agree that increased physical activity may contribute to increased caloric needs and relapse in women with anorexia nervosa. In fact, in an earlier article, one of us (1) reported that physical activity, as measured by counts of movement using an acceleration-sensitive device with a solid state memory worn on the waist, was positively correlated with calories required to gain weight in anorexic subjects. Nevertheless, we did not measure physical activity in this study because we know of no method that can accurately measure the amount of energy used in physical activity in a free living environment.

The aim of this study was to measure caloric needs necessary for weight maintenance in anorexia and bulimia nervosa patients by measuring actual caloric intake. While a formula can be used to estimate the amount that physical activity contributes to daily energy expenditure, using such a formula may

be problematic. That is because other factors may contribute to increased caloric requirements in short-term recovered anorexic women; for example, increased resting metabolic rate or increased thermogenic response to ingested food (2). Overall, factors that contribute to increased caloric needs in short-term weight-recovered anorexic women remain to be characterized.

Insofar as we know, the choice of which tables to use to compare eating disorder patients to the general population is relatively arbitrary. To our knowledge no study has characterized an "ideal body weight" in anorexia. Body weights for similar frames are several kilograms greater in the 1983 tables as compared to the 1959 tables. Our clinical experience is that getting anorexic patients to gain to between 95% and 100% of the 1959 tables is adequate for reversing malnutrition. No data suggest that having anorexic patients attain the normative mean of the higher 1983 Metropolitan Life Tables would make any meaningful difference in terms of physiological improvement, such as normalization of reproductive function. In fact, adopting the 1983 tables could potentially increase length of treatments and increase resistance to suggested target weights in eating disorder patients.

We do not disagree with the use of either the 1983 or 1959 tables. We are currently conducting studies aimed at better understanding the relationship between normalization of body weight and physiological function, such as return of reproductive function, in women with eating disorders. A better understanding of the relationship between body weight and treatment response would significantly help clinicians in recommending maintenance weight for women with anorexia nervosa.

Treatment of Neuroleptic-Resistant Mania and Schizoaffective Disorders

SIR: E.S. Garza-Treviño, M.D., and associates (1) have reported that verapamil is as effective as lithium in the treatment of acute mania. They mention that during their study, seven out of the 12 patients treated with verapamil received a combination of haloperidol and lorazepam to control excessive agitation.

Over the past several years I have investigated the effects of a calcium channel antagonist, nifedipine, in neuroleptic-resistant schizoaffective patients and in manic patients who were slow to respond to neuroleptic medication. I chose nifedipine because it has been reported to have depressant effects in normal persons (2). I have so far studied seven patients, all of whom have been treated with high doses of several neuroleptics with no improvement after at least 10 days of treatment (Brief Psychiatric Rating Scale [BPRS] scores still remaining above 60). The dose of nifedipine used was 120 mg/day, given

orally. Two of the seven patients rapidly and dramatically improved after nifedipine administration (in 48 hours) and three consistently improved, but more slowly. Nifedipine had no obvious effects in the last two patients. Nifedipine was withdrawn in all the patients before they were discharged. Two of the patients who had responded favorably (one of them in less than 48 hours) to the neuroleptic-nifedipine combination relapsed 12 and 18 months, respectively, after discharge. For 3 days following readmission, they were given nifedipine without neuroleptics, and this treatment alone had no effect.

This short study shows that the effects of neuroleptics in some patients can be enhanced, sometimes dramatically, by the addition of a calcium channel antagonist. Nifedipine alone does not appear to have rapid antimanic effects. Although the procedure I used is quite different from that of Dr. Garza-Treviño and associates, I suggest that the addition of haloperidol in their verapamil-treated patients may have been more than an adjunct to control the behavior. Haloperidol could have interacted with verapamil and resulted in the two drugs mutually potentiating each other. I do not think this reduces the interest of the work of Dr. Garza-Treviño and associates, but I think that discussions about the antimanic effects of calcium channel inhibitors should clearly differentiate the proper effects of these drugs from those of neuroleptics, since animal studies show that their action on locomotor activity can be either totally different (3) or related through an interaction on dopamine receptors (4).

RENAUD DE BEAUREPAIRE, M.D., PH.D.
Caen, France

Dr. Garza-Treviño and Associates Reply

SIR: Dr. de Beaurepaire has raised the possibility of a pharmacological synergism between haloperidol and verapamil having affected the treatment responses in our study comparing verapamil versus lithium in a randomized sample of 20 bipolar patients in the acute phase of a tic episode. This is an interesting idea which possibly deserves further investigation. However, it is important to emphasize that only three of the 12 verapamil-treated patients received most of the adjunctive medications in our study. (Five of these patients received no adjunctive medications, three received one dose, and one each received three, five, eight, and nine doses. Of the eight lithium-treated patients, three received no adjunctive medications, two received one dose, and three received three doses.) Those three patients receiving the most doses of adjunctive medications also scored higher on the Petterson Mania Scale than the rest, and their adjusted analysis of covariance (ANCOVA) posttreatment values changed less than the average. For those reasons, their scores

did not significantly affect the results of our study (nonsignificant difference between treatments). The same conclusion would have followed if those three patients in the verapamil group had been left out of the statistical analysis. The pretreatment (unadjusted) means of the BPRS were 40 for verapamil and 33 for lithium, and the Petterson Mania Scale scores also showed that, by chance, the verapamil group was more severely ill. Higher baseline scores provide greater possibility for improvement and can contribute to an apparent treatment effect (1, 2). Consequently, the measures had to be adjusted by ANCOVA. Following statistical adjustment, we noted a slight trend to favor lithium in our data, partly due to the fact that the three verapamil patients who received the most frequent adjunctive haloperidol evidenced relatively small covariance-adjusted change. However, the overlap between the groups was so great that larger samples would be required to demonstrate a statistically significant difference. Using appropriate formulas, it was determined that a sample size of 40 patients per group would be required to achieve a power of 0.80 for a treatment effect as great as that observed in this study. In that light, the observation of Dr. de Beaurepaire based on six patients is interesting, but hardly conclusive.

Nevertheless, we believe that Dr. de Beaurepaire has added to previous evidence (3) that other calcium channel blockers (e.g., nifedipine) have antimanic effects, though they act synergistically with other conventional treatments for mania. This should provide further stimulus to investigate whether there is indeed a role for calcium channel antagonists in the treatment of the lithium-resistant patient population. Further studies should clarify the issues of efficacy and possible synergistic effects.

Automobile Driving by Psychiatric Patients

SIR: We read with great interest the letter by Leo E. Hollister, M.D. (1), concerning driving by psychiatric patients. Dr. Hollister points out that textbooks of psychiatry lack any guidelines concerning traffic accidents related to psychiatric impairment. However, we managed to find many articles that addressed the question of accident proneness among psychiatric patients, one of them in the *Journal* (2). Psychiatric patients with personality disorders and paranoid disorders were reported to be at risk of having traffic accidents (2, 3).

Edlund et al. (4) found a greater rate of traffic accident involvement among 103 schizophrenic patients compared to a control group. They reported that schizophrenic patients drive substantially less than controls and thus may be at

greater risk of motor vehicle accidents per miles driven than age-matched controls. Schlosberg (5) reported equal rates of traffic violations and accidents in a group of schizophrenic patients and a control group, but he did not take into consideration the difference in miles traveled in the two study groups.

Many methodological problems arise in the field of accident proneness research. We must take into account issues such as diagnosis, drug therapy, recent stress, exposure, etc. These issues render accident proneness research an intriguing challenge for public health officials and explain why no conclusion has yet been drawn.

We agree with Dr. Hollister that this issue cannot any longer be evaded. However, the patient and the patient's family should not be responsible for this matter, even if they are the first to recognize the driving limitations. Giley et al. (6) reported that many patients with dementia do continue to drive, even when impaired. Thus, physicians in our opinion are responsible for the well-being of their patients and the welfare of society. In this instance the rights of the society should prevail over the rights of the individual. We conclude that psychiatrists and other physicians should take a more active role in the battle against traffic accidents. Education, research, and referral to driving fitness assessment with the medical and licensing authorities should all be a part of a greater involvement of the medical profession in order to combat traffic accidents.

DR. IANCU IULIAN

DR. WIENER ADA

Tel Aviv, Israel

Dr. Hollister Replies

SIR: Is my face red? How could I have missed the three additional references pertinent to driving by psychiatric patients which are cited by Drs. Iulian and Ada? Probably no one doubts that, as a group, psychiatric patients of all kinds would have a higher rate of automobile accidents than unaffected persons. The problem comes in making a determination in an individual case. I did not mean to imply that the patients' opinions should be sought but rather those of the persons closest to them. Relatives and friends might be aware of problems which could escape detection during the usual psychiatric visit. As most psychiatric patients drive with insurance protection furnished by relatives or friends, the latter should be highly concerned about the patient's fitness to drive. The psychiatrist can make a better judgment about the issue of driving if these additional sources of information are consulted. They

might also be the strongest allies in enforcing any recommended restriction on driving.

Houston, Tex.

Steroid Use and Aggression

SIR: We read with great interest the case reported by J. Thomas Dalby, Ph.D. (1), of a sustained aggressive and antisocial reaction in a 20-year-old man after "brief exposure to a low dose" of the anabolic steroid Equipoise. However, based upon the subject's self-administration schedule and the pharmacologic profile of Equipoise, he was not exposed to a "low" dose nor was this exposure "transient," which brings into question the author's interpretation of the case.

Equipoise (boldenone undecyclate) is an injectable veterinary anabolic agent marketed primarily for use in the treatment of debilitation in horses. Despite its status as a veterinary drug, we have found that it is commonly diverted to the steroid "underground market" for human use. The compound is a depot anabolic agent formulated in sesame oil. It has a rapid onset of action, yet provides relatively stable high drug concentrations over a prolonged time period. The package insert from the manufacturer notes that, at the recommended dose of 0.5 mg/lb of body weight administered every 3 weeks, over-aggressiveness (in horses) is a potential adverse reaction to Equipoise. This aggressiveness may persist for 6–8 weeks after drug administration.

As cited in the case report of Dr. Dalby, this man was self-administering Equipoise on a 5-week escalating dosage schedule, ($\frac{1}{2}$ cc per day, 4 days a week, with increments of $\frac{1}{2}$ cc per week). Assuming that he used the 50 mg/ml formulation, he received 100 mg of Equipoise the first week of the cycle, 200 mg the second week, 300 mg on the third week, 400 mg on the fourth week, and 500 mg on the fifth week. Consequently, this individual took a total incremental dose of 1500 mg of a long-acting anabolic steroid, which for a 150 lb man, would be an amount that is 20 times higher than that which may produce long-term aggression.

Dr. Dalby's assertion that anabolic steroids have the potential for inducing behavioral effects when administered "even in limited quantities" seems misconstrued given the significant amount of steroid self-administered by the subject in this case report. The fact that the drug effects persisted beyond the immediate period of self-administration may plausibly be explained by significant drug accumulation due to the subject's rapid incremental multiple dosing schedule and the long half-life of the depot steroid preparation (2).

HOWARD B. MOSS, M.D.
GEORGE L. PANZAK, R.N., M.S.
Pittsburgh, Pa.

Dr. Dalby Replies

SIR: Several clinical reports have demonstrated the adverse behavioral effects of anabolic androgenic steroids in athletes

and body builders. Uzych (1) noted that steroids are typically used by these individuals over an extended time period (8–240 weeks) and at dosage levels 10–100 times greater than therapeutic levels. Most steroid users combine or "stack" several steroids concurrently. I reported a case of a young man who showed sustained, radical behavioral change after his use of a single steroid of a dose low by human-use standards (2) for only 5 weeks. No previous report had shown a steroid-correlated transformation with such casual use. Dr. Moss and Mr. Panzak question whether my case can be considered as an example of brief exposure or low dose. The steroid used (Equipoise) is an equine preparation, and Dr. Moss and Mr. Panzak employ the manufacturer's suggested dose for horses and convert it to a human equivalent. The result, they conclude, is that the patient I reported had received a relatively high dose (compared to horses) and for a longer period than suggested by the manufacturer. Interspecies comparisons of drug response are rarely simple due to the many metabolic differences that exist. It seems clear that human users have paid little attention to the manufacturer's suggestions about use in establishing preferred dose. Dr. Moss and Mr. Panzak assist us by pointing out that what human users of steroids have established as "low" doses may be anything but. The behavioral response I reported is likely very common (in humans as in horses) and, as my case noted, the behavioral response of both humans and horses could persist beyond the period of drug use. The argument against any innocent use of these substances is thus strengthened.

Calgary, Alta., Canada

Organic Mental Disorders

SIR: Robert L. Spitzer, M.D., and associates (1) proposed to retire the term "organic mental disorders," which, according to them, "implies an outmoded mind-body dualism." Ironically, their proposal is confounded by the same mind-body dualism that they wish to overcome.

For example, in Alzheimer's disease, the authors would have us believe that dementia is a "secondary disorder," i.e., that the disease "causes" the dementia as its "effect." Therefore, patients with Alzheimer's disease would continue to be coded twice, once for Alzheimer's disease and again for dementia. In fact, there is only one disease and an unresolved semantic muddle.

Furthermore, if the mental aspects of Alzheimer's are secondary to the physical lesions, so are physical aspects, such as shouting, myoclonus, and gait disturbances. The physical and mental manifestations of Alzheimer's are merely two sides of the same illness. Such usage of "secondary" only expresses a truism—that clinical features of diseases are "secondary" to pathological findings. Additionally, the brain lesions of Alzheimer's are secondary to the etiology agent(s), but this is also a truism.

The conceptual muddle of the "organic mental disorders" remains because the problem is not where these authors at-

tempt to locate it. They have not noticed that *DSM-III-R* and the *ICD-9 Classification of Mental Disorders (ICD-9)* are both manuals of "disorders," a situation which is almost unique in medical practice. There are nine categories of "disease" in *ICD-9* (such as diseases of the circulatory system), and only two categories of "disorders" (endocrine, nutritional, and metabolic disorders, and mental disorders). Physicians generally diagnose "disorders" when there are functional rather than structural problems (e.g., an epigastric "disorder" as compared to ulcers). Except for psychiatrists, medical colleagues never refer to Alzheimer's disease as a "disorder."

Unlike "disorder," the term "disease" refers to a pathological process in a patient that has an etiology, specific symptoms, and host-resistance factors. This works for Alzheimer's disease and for other "organic mental disorders" but not for histrionic personality disorder or hypochondriasis. And while the day may come when the term "disease" will apply to schizophrenia, it does not do so at present.

Regarding the "organic disorders," Karl Jaspers' (2) decades-old proposal for three groups (axes?) of psychiatric illnesses is worth reviewing:

1. Known diseases with psychic disturbances. This category includes cerebral illnesses such as Alzheimer's disease; systematic diseases such as uremia; and "poisons" such as alcohol intoxication and carbon monoxide.

2. Schizophrenia and manic-depressive illness. While these do not yet qualify as diseases, the notion of a disease can function as a "guiding idea" through which they can be studied and treated.

3. Everything else. The notion of a disease can still guide investigations, although there are no clear-cut boundaries between these psychiatric problems and other nonpsychiatric problems and we are far from appreciating etiology, pathophysiology, or host-resistance factors.

MICHAEL ALAN SCHWARTZ, M.D.
New York, N.Y.
OSBORNE P. WIGGINS, PH.D.
Louisville, Ky.

SIR: I read with interest the Commentary by Dr. Spitzer and colleagues regarding the proposed classification of organic mental disorders in the *DSM-IV* because of its relevance to the field of developmental disabilities. Individuals with severe or profound disabilities may present, for example, with drug-responsive aggressive or self-injurious behavior. These behavioral disturbances can be manifestations of primary neuropsychiatric syndromes in which irritability, overactivity, and other disruptions in CNS function are the primary features (1-3). The need to establish an appropriate diagnostic category for these disorders is an important clinical issue because there are, in many states, medicolegal mandates requiring that developmentally disabled individuals be given a psychiatric diagnosis before any drug treatment is initiated. In the *DSM-III-R* these individuals could be given a diagnosis of organic mental syndrome.

Although I agree in principle with the proposal by Dr. Spitzer and associates to differentiate between primary and secondary disorders, it is not clear to me how they propose to categorize the neuropsychiatric syndromes I have described. The proposed *DSM-IV* category, "secondary personality change due to a nonpsychiatric medical condition (4)," is one possibility, but I would argue that it is inappropriate to classify disorders whose first manifestations may begin during infancy and persist throughout life as secondary. Subsuming them under the category of mental retardation would also be inappropriate because they are not intrinsic behavioral disturbances associated with developmental disabilities. I would suggest that the *DSM-IV* provide a distinct category, independent of the primary versus secondary dichotomy, for these disorders.

ROBERT SOVNER, M.D.
Medford, Mass.

SIR: The arguments of Dr. Spitzer and colleagues favoring deletion of the term "organic mental disorders" in *DSM-IV* suggest that these colleagues, like many wise philosophers both ancient and modern, remain troubled by the dilemma of the mind-body relationship (1). Despite their inference that Cartesian mind-body duality belongs to the past and that organic-nonorganic distinction is irrelevant because "of the growing body of evidence of the importance of biological factors in the etiology of major 'nonorganic' mental disorders," psychiatry cannot maintain its credibility unless there is differentiation between mental illness produced by verifiable biological causes and mental disorders related to the human condition and understandable in terms of psychological reactions to intrapsychic conflict, disturbed interpersonal relationships, or other adverse environmental factors.

The use of organic terminology implies the assumption of medical responsibility as the means for primarily alleviating or curing the illness. Nonorganic terminology implies patient responsibility toward restoration of normal mental function assisted by psychosocial support systems and, if necessary, symptomatic relief by the use of psychotropic medications. Eliminating the organic-nonorganic dichotomy will fuel skepticism that myriads of variant human behaviors are being medicated by psychiatrists simply because of presumed biology and thus absolving patients from self-responsibility for psychological rather than biologically proven mental disorders.

Despite its extensive use and popularity, *DSM-III* and its progeny have not escaped criticism (2, 3). Adding to *DSM-III*'s emphasis upon empirical description and ignoring causation by eliminating organic-nonorganic dichotomy (essentially the mind-body conflict) produces a woolly categorization of disorder.

ders that the authors mentioned (schizophrenia, hypothyroidic depression, and substance-related brain disorders) into their new classification of "primary," "secondary to a nonpsychiatric disorder," and "substance-induced disorder." No matter how useful such a ploy might be in preventing disharmony between the different schools of psychiatry, it represents an escape route when questions about whether functional major mental disorders are really biological arise. At least the term "nonorganic" differentiated from "organic" undeniably implies that psychiatry is not certain of an underlying organic basis for major functional mental disorders such as schizophrenia, this despite findings of associated brain abnormalities by no means proving causality (4, 5). I fear that under the cloak of "organic mental disorders" it is really the term "nonorganic mental disorders," with the obvious problem that the biological nature of these conditions is far from proven, that Dr. Spitzer and his coauthors wish to retire.

THEODORE PEARLMAN, M.D.
Houston, Tex.

SIR: Dr. Spitzer and colleagues proposed eliminating the term "organic" and reorganizing the classification of organic mental disorders in *DSM-IV*. While I am in sympathy with their proposal in general, some aspects of it deserve closer examination.

First, the authors define secondary disorders as "due to medical disorders that are classified outside the mental disorders section of *ICD* (e.g., brain tumor, vascular disease, metabolic disturbance)." Their use of "secondary" here implies that the physical condition (nonpsychiatric medical disorder) should have an etiologic relationship (possibly pathophysiologic) with the secondary mental disorder. However, while acknowledging that it is often difficult to make a judgment about the etiologic role of physical conditions in mental disorders, Dr. Spitzer and colleagues do not provide any guidelines with which to test whether a physical condition has an etiologic relationship with a mental disorder. This lack of specific guidance has also been a limitation of *DSM-III* and probably reflects the incomplete nature of our understanding of this area.

Second, the relationship between a physical condition and a mental disorder often becomes more complex the more it is studied. For example, in the study of mood disorder following stroke, while early reports suggested a specific association between brain lesion characteristics and depression, further work has not always reproduced the lesion findings and has highlighted the role of other potential etiologic factors. These risk factors include family history of affective disorder, past psychiatric history, premorbid personality neuroticism traits,

negative life events (beyond the stroke itself), inadequate social support, and severity of disability, particularly among males. The findings indicate that the effects of stroke (such as threat to life, loss of function, role disruption) other than direct brain injury are also important in vulnerable individuals. Thus, given the complexities outlined above and the current lack of clear guidelines to determine the etiologic role of a physical condition, I suspect that the term "secondary" will often have little meaning other than a temporal relationship.

Third, in part, Dr. Spitzer and colleagues justify their introduction of secondary disorder by suggesting it will direct the clinician to the detection and treatment of underlying physical disease. While their intent is laudable, I wonder whether we need to design a classification system to address this issue of differential diagnosis. Perhaps undergraduate, residency, and continuing medical education would be a more appropriate vehicle?

Fourth, by limiting the category of secondary disorders to those with a relationship to physical conditions, Dr. Spitzer and colleagues introduce an etiologic component to *DSM-IV*. This seems to be a move away from the descriptive nature of *DSM-III* and *DSM-III-R*. However, to be consistent, other potential etiologic factors should also be given due recognition in the new classification.

Finally, like Fogel (1), my inclination would be to maintain a descriptive axis I nosology. If an etiologic subclassification for each mental disorder is required, then a list of possible etiologic factors (physical, psychological, and social) based on the available empiric evidence could be provided. Depending on the case at hand, the clinician would note the applicable factor(s), recognizing that in many cases the etiology would be unknown.

PHILIP L.P. MORRIS M.D., Ph.D.
Baltimore, Md.

SIR: The proposal by Dr. Spitzer and associates to drop the term "organic mental disorder" from the *DSM* is well stated and deserving of further study and favorable consideration.

However, careful thought also should be given to possible opportunistic misinterpretation of these well-intended refinements by third party payers seeking simplistic and self-serving words to justify perpetuation of discriminatory health care coverage of mental illness.

The precise meaning and intent of these conceptual and linguistic changes should be clearly defined in any future diagnostic manual to minimize and counteract predictable legal arguments challenging favorable court decisions based on a physical-medical model of many major mental illnesses.

THOMAS T. TOURLENTES, M.D.
Galesburg, Ill.

SIR: Finally! Dr. Spitzer and colleagues' advocacy for eliminating the term "organic mental disorders" in *DSM-IV* is a long-overdue expression of common sense combating anachronistic obfuscation. There is no rational reason that schizophrenia and bipolar disorder should be labeled "functional" as opposed to "organic": at best this misleadingly suggests

causal explanations running counter to current consensus understanding; at worst it interferes with treatment and promotes inappropriate guilt in patients and their families.

One implication of this elimination not mentioned by Dr. Spitzer and colleagues, salutary in my opinion, would be the effect on admission criteria for various health facilities, e.g., state hospitals. Beleaguered though many of these institutions may be, their now-popular adoption of the adjective "organic" in front of any principal psychiatric diagnosis serving as an exclusionary criterion for admission, has been a cynical solution. This has encouraged misplaced attitudes of entitlement in accepting institutions' staff and promoted frustration and manipulation of diagnoses on the part of sending institutions' staff (often also beleaguered). We truly have enough difficulties with cynicism arising from external challenges without having to generate more for ourselves. Eliminating the "organic" terminology will at least repair an artificial division: the patient chronically psychotic following head trauma, surgery or stroke, etc., should not be arbitrarily excluded from the same range of dispositions as that of someone with schizophrenia. Rather, transfers and placements should be based on individualized, reasoned clinical judgments and criteria.

I'm less enthusiastic about the proposed use of "primary" and "secondary": why should mania following a stroke be considered "secondary" and mania proceeding from its undiscovered cause or causes be called "primary"? Admittedly, however, a better alternative has not occurred to me.

Emboldened by Dr. Spitzer and colleagues' laudable and ambitious proposed terminological reform, would it be too much to hope that we might consider an alternative to the term "schizophrenia"? "Split mind" is hardly an accurate or neutral image, and this etymological derivation has hopelessly popularized confusion with "multiple personalities" in common parlance and "humor" in the media. This has only added to shame and stigma for patients and their families. We could resurrect the variously used but more appropriate "paraphrenia," or find a new coinage.

WILLIAM M. GREENBERG, M.D.
Paramus, N.J.

Dr. Spitzer and Associates Reply

SIR: We appreciate this opportunity to respond to the very thoughtful comments on our article.

Drs. Schwartz and Wiggins suggest that our proposal is confounded by the same mind-body dualism that we wish to overcome. A mind-body dualism, which we agree is outmoded, is not the same as the dualism that our proposal perpetuates: the practical distinction between disorders/diseases classified within the mental disorders section of ICD and those classified outside. The suggestion that, for example, a depressive syndrome that is attributed by the clinician to hypothyroidism should be called "secondary depressive disorder due to hypothyroidism" (rather than "organic depressive disorder" as in *DSM-III-R*), has practical utility: it directs the clinical attention to the underlying endocrine condition. We fail to see how this is a perpetuation of a mind-body dualism.

Of course, saying that Alzheimer's disorder (the *DSM-IV* mental disorder) is due to Alzheimer's disease (the neurologic disorder) conveys no useful information. What Drs. Schwartz and Wiggins overlook is that Alzheimer's disorder (disease) is unique in that, ever since *DSM-III-R*, both psychiatry and neurology have insisted that the condition be classified within

their section. The Solomonesque solution to this turf battle was to include the disorder in both sections with slightly different wording, leading to the semantic muddle for this disorder that Drs. Schwartz and Wiggins refer to. However, numerous other examples illustrate the utility of our proposal for other dementias, such as the dementia due to HIV infection, head trauma, or endocrine disturbance.

Finally, Drs. Schwartz and Wiggins are uncomfortable with *DSM's* lumping of true diseases (e.g., the "organic mental disorders") with possible diseases (e.g., schizophrenia) and with supposed nondiseases (e.g., histrionic personality disorder), all under the umbrella rubric of "disorders." They would have us reconsider Jaspers' proposal for three groups, but we fail to see how such a proposal is relevant to the issue of whether our terminology, "secondary disorders," is preferable to the *DSM-III-R* terminology of "organic mental disorders."

Dr. Sovner asks how, with our proposal, *DSM-IV* would classify individuals with severe developmental disabilities which are manifestations of "primary neuropsychiatric syndromes." If the clinician judges that the disabilities are due to a diagnosable neurologic or other condition classified outside of the mental disorders section (e.g., secondary to head trauma, cerebral palsy), the diagnosis would be either "secondary personality change" (if there is an identifiable change in personality functioning) or else, "secondary disorder, not otherwise specified." The tougher problem is when there are symptoms (such as "soft signs") that suggest a neurologic disturbance, but inadequate data to confirm the existence of a particular neurologic diagnosis. There is no adequate diagnosis for such cases, which in both *DSM-III-R* and *DSM-IV* would by default be termed, "mental disorder not otherwise specified."

Dr. Pearlman appears to wish to perpetuate the very dualism that our proposal is designed to overcome. He believes that our proposal will inhibit attempts to answer a question that he regards as meaningful: whether "functional mental disorders" are really biological." We believe such a question is no longer appropriate and would sharply disagree with his notion that only patients with nonbiological disturbances have some responsibility for restoration of normal functioning. Does not the patient with diabetes or coronary artery disease (biologic disorders) have some responsibility for lifestyle changes and medication compliance that involve responsibility?

Dr. Morris is correct in noting that our proposal does not help the clinician make the extremely difficult *DSM-III-R* judgment as to whether a coexisting nonpsychiatric medical disorder is etiologically related to a presenting behavioral disturbance. Hopefully, the *DSM-IV* text will provide some useful guidelines to what will always be a difficult clinical decision. We would argue, however, that as difficult as the distinction often is in clinical practice, it has important educational and treatment implications that need to be preserved, in some form, in our nosology. Perhaps it would be better to make the etiologic distinction a subtype of a purely descriptive classification, as Fogel has suggested, and include, as Dr. Morris suggests, other potential etiologic factors, such as psychological and social factors. However, our proposal had to maintain consistency with the overall classification of *ICD-10*. Furthermore, noting the presence of etiologic, psychologic, or social factors for disorders in all of the major diagnostic classes, as Dr. Morris suggests, is unlikely to have as clear prognostic and treatment relevance as noting the presence of an etiologic nonpsychiatric medical disorder, which is the essence of our proposal.

We share with Dr. Toulentès the concern that the *DSM-IV*

will be scrutinized by third party payers in order to justify perpetuation of discriminatory health care coverage of mental illness. We would hope that our proposal could be used to further underscore the basic principle that biological factors may be of importance in *all* mental disorders.

Dr. Greenberg notes that one salutatory effect of our proposal will be to foil attempts of some psychiatric facilities to inappropriately exclude psychiatric patients from care who have "organic" problems. Emboldened by our attempts at terminologic revision, he proposes doing away with the term "schizophrenia." Like many traditional terms (e.g., conversion disorder, multiple personality disorder), one has to balance the advantages of familiarity and historical tradition with the advantages of picking a term that is more technically precise. In the case of schizophrenia, its long historical tradition and, in our judgment, no suitable alternative term, would seem to us to justify its continued use. Finally, we are also not entirely satisfied with the term, "secondary," but like Dr. Greenberg, we have been unable to come up with a better alternative.

Dopamine in Schizophrenia

SIR: In their article on the role of dopamine in schizophrenia, Kenneth L. Davis, M.D., and associates (1) reviewed relevant neurochemical studies. I recently performed a similar review (2) and came to a somewhat different interpretation. Dr. Davis and associates interpreted the evidence to suggest that mesocortical dopamine pathways may be deficient in schizophrenia, while mesolimbic dopamine pathways are overactive. My interpretation was that overall dopamine output is both deficient and hypervariable with periods of effective hyperdopaminergic function during acute exacerbations. These periods of effective hyperdopaminergic function could result from relative increases in dopamine release impinging on supersensitive postsynaptic receptors. Reduced dopamine output could cause postsynaptic supersensitivity by chronic synaptic depletion of transmitters.

Several factors are not fully explored by Dr. Davis and associates. First, their interpretation is based on an assumption that elevated dopamine levels in post-mortem studies indicates hyperdopaminergia when in fact it more likely indicates the opposite. Pharmacologic studies in animals demonstrate that when dopamine turnover is varied, dopamine levels and dopamine metabolite levels have an *inverse* relationship implying a build-up of unreleased dopamine when turnover decreases (3). The interpretation that increased dopamine levels indicates hypodopaminergia is supported by a study which showed that cerebrospinal fluid levels of dopamine-sulfate and dopamine metabolites vary inversely relative to various symptoms in schizophrenic patients (4). Other essential concepts in interpreting these studies involve the dynamic nature and longitudinal course of schizophrenia. Most studies of dopamine metabolite levels have found no difference in the dopamine turnover of schizophrenic patients and controls. However, these studies were generally performed on schizophrenic patients admitted for acute psychosis. Dopamine turnover

correlates positively with acute positive symptoms and negatively with chronic negative symptoms and severe pathology. Longitudinally, dopamine turnover falls with recovery from acute exacerbations whether or not neuroleptics are utilized (5). Furthermore, dopamine turnover decreases with age in schizophrenic patients but increases with age in normal controls. Schizophrenic patients who are older or have more chronic negative symptoms tend to have fewer acute exacerbations. Most studies have therefore selected a biased sample of patients, who have relatively high dopamine turnover and tested them when their dopamine turnover was relatively increased. Studies of chronic treatment-refractory schizophrenic patients have consistently demonstrated reduced dopamine turnover. This all suggests that in the baseline state, all schizophrenic patients have some degree of reduced dopamine turnover. No study has found evidence of increased dopamine transmission in schizophrenia.

These two interpretations are not necessarily at odds. It is quite likely that a disorder resulting in deficient dopamine output would affect the various dopamine tracts differently due to different protein populations (receptors, second messengers, cotransmitters, etc.), neurocircuitry, and regulatory mechanisms. Furthermore, a dopamine deficiency could lead to brain areas with hyperactivity if dopamine is acting as an inhibitory transmitter for that area (6). As a principal foundation, however, I believe that the interpretation that dopamine output is deficient and hypervariable is more consistent with the clinical experience of schizophrenia, an illness of chronic symptoms with acute exacerbations, and with the reviewed studies.

ANDREW J. HERITCH, M.D.
Milwaukee, Wis.

Dr. Davis Replies

SIR: Dr. Heritch states that in his review on the role of dopamine in schizophrenia he reached a "somewhat different conclusion" than we did in our review. Dr. Heritch hypothesizes that dopamine output is both deficient and hypervariable, with increased dopamine function during exacerbations. In fact, this conclusion shows important similarities with ours, except that we proposed specific anatomical areas of increased and decreased dopamine activity, as well as a unifying hypothesis linking the two conditions. Specifically, we proposed decreased prefrontal dopamine activity (clinically reflected as

negative, deficit symptoms) and increased mesolimbic dopamine activity (clinically reflected as positive symptoms) to co-occur. We have hypothesized that the two conditions may be linked, i.e., decreased prefrontal dopamine function may lead to disinhibition of subcortical dopamine activity. Recently another attempt has been made to link states of decreased and increased dopamine activity, which appears to elegantly complement our hypothesis. Grace (1) hypothesized that decreased tonic activity of (predominantly prefrontal) dopamine neurons (clinically reflected in negative symptoms) would lead to compensatory upregulation of the dopamine system (predominantly subcortically) which would make it more sensitive to increased phasic release of dopamine (clinically expressed as positive symptoms).

The statement by Dr. Heritch that the post-mortem studies suggest decreased dopamine function is based on studies examining dopamine, not its metabolite, homovanillic acid (HVA) in post-mortem brain. Most post-mortem studies found both dopamine and HVA to be increased, suggesting increased dopamine turnover. Whether this also implies increased dopamine function depends on the state of the various dopamine receptors. Although studies have so far been confined to dopamine 1 and dopamine 2 receptors, their results suggest that dopamine 2 receptor sensitivity is increased in schizophrenic brains.

In summary, we agree with Dr. Heritch that states of decreased and increased dopamine activity can co-occur. However, we feel that our hypothesis as well as that of Grace linking different states of dopamine function to specific anatomical areas linking the two conditions has heuristic value until it will be replaced by other, more sophisticated, models.

Amobarbital Interview for Catatonic Patients

SIR: W. Vaughn McCall, M.D., and associates (1) are to be commended for their study of the amobarbital interview for catatonic patients. Revisiting old procedures is a valuable contribution.

I do wish to raise a question about the design of their study. Do they really believe subjects could not distinguish a saline infusion from an infusion of sodium amytal? Or that the "blind" judges did not notice the slurred speech, facial musculature relaxation, sleepiness, nystagmus, etc., that occur with the active substance? I seriously doubt it. What they in fact have is an experimental procedure that compares the response to a heavily tranquilizing medication to a substance that produces no pharmacological effects.

Aside from the significant biochemical differences that such a design results in, there is the very simple effect of the *experience or sensation* of sedation on a psychotic individual. How did the patients interpret this sensation? I would propose a simple counter-hypothesis. Those patients who were responders felt compelled or assisted in speaking as a response to the powerful sensations that the amytal produces. My experience with catatonic patients is that they are very preoccupied with notions of control and the impact of their voluntary move-

ments on maintaining control. For example, a common catatonic delusion is the belief that movement of any kind will result in world destruction. Given this belief system I do not think it unreasonable to suppose that the experience of the physician or investigator effecting the "heaviness" of their limbs via sedation might have a significant impact on their behaviors.

The failure of the authors to include a psychological hypothesis is part of a larger issue regarding the scientific validity of double-blind studies. Should we begin to consider that a "valid" double-blind medication procedure must involve inquiring whether the judges and subjects can determine experimental from control medication and what their expectations regarding each are?

MICHAEL SACKS, M.D.
New York, N.Y.

Dr. McCall Replies

SIR: Dr. Sacks is correct in assuming that most of the subjects in our report had nonspecific signs of sedation while receiving amobarbital such as muscular relaxation, sleepiness, and slurred speech. Remember, however, that all the subjects were mute upon entry into the study; hence any sustained speech production (slurred or unslurred) must be taken as evidence of a therapeutic effect which was not seen with the placebo injection. Second, it may be difficult to distinguish between catatonic unresponsiveness and true sleep; sleepiness per se, therefore, did not routinely undo the blind method. Furthermore, the finding of the superior effectiveness of amobarbital compared with placebo was confirmed by an independent rater of the videotaped interviews. The additional "distance" interposed between the subjects and the rater by the videotape helps to eliminate some of the subtle clinical nuances that can only be felt when a rater is actually in the interview room with the subject. I believe this "distance" helped to ensure the blindness of the videotape rater. Dr. Sacks also questions that the subjects' response to amobarbital was a specific pharmacologic response (e.g., GABA-ergic), but may be instead a result of the subjects' interpretation of the nonspecific sedative effects of the drug as an opportunity to stop catatonic behavior. We were careful to state in our paper that there is not sufficient evidence to support the involvement of a specific neurotransmitter system. On the other hand, the combination of placebo and suggestion was insufficient to relieve catatonic symptoms. We reasoned, therefore, that some change in the patient's physiology was necessary for the rapid relief of catatonic mutism, and that neither a patient's expectations nor a purely psychologic intervention alone was sufficient. Whether a change in a patient's physiology (e.g., with amobarbital) alone is sufficient to break catatonia, or whether a physiologic change must be coupled with a patient's fertile expectations is an interesting but unanswerable question.

W. VAUGHN MCCALL, M.D.
Winston-Salem, N.C.

Anne Sexton's Biography

SIR: In the book review by Donald W. Goodwin, M.D. (1), of *Anne Sexton: A Biography*, Dr. Goodwin discusses Sexton's therapy and many diagnoses and writes of her psychiatrist Martin Orne, M.D., whose audiotapes of 300 therapy hours with Sexton were given to her biographer without her written consent. I am familiar with the arguments that have appeared in the press and medical journals about his behavior in releasing not only the tapes but also his clinical notes. The reviewer makes this defense: "He had the family's consent. Self-revelation was Sexton's forte—no one (sic) doubts she would have approved. Orne didn't receive a penny in compensation. For a true confessor, perhaps the more to confess about the better. If so, nothing could have pleased Anne Sexton more than this most revealing of biographies."

To state that "no one doubts she would have approved" is a fantasy. I doubt it. So have others. When do children have the rights to their parent's psychiatric notes? Sexton's daughter's relationship with her mother was at best problematic. Sexton did not even know of the existence of the tapes in Orne's possession. If it is true that, as Dr. Goodwin says, "for a true con-

fessor, perhaps the more to confess the better," why don't we hear about her sexual liaison with her next psychiatrist, which she confesses she wanted to expose. Why did the reviewer fail to mention this affair of the so-called true confessor? Is not *this* story of importance to the readers of the *Journal*?

The psychiatric profession is repeatedly attacked by many people as lacking the ability to implement its honorable and well-known ethics of confidentiality and condemnation of sexual exploitation. As Dr. Goodwin says, "Orne didn't receive a penny" in compensation for release of records and tapes. But her other psychiatrist got his regular fees for his service. I find that this enthusiastic review does a disservice to psychiatry by closing one eye. You do not hide shame by sham.

Corrections

In the reply by Owen M. Wolkowitz, M.D., et al. to the letter "Antiglucocorticoid Effects of DHEA-S in Alzheimer's Disease" (August 1992, p. 1126), there are several changes involving references. In the 20th line of the second paragraph, reference "2" rather than "4" should follow the word "rats," and in the next line, references "5" and "6" should follow "activities." In the third paragraph, the first sentence should end with reference "7." On the ninth line of that paragraph reference "6" should follow the word "imbalances" and in the next line reference "7" should follow "pregnenolone." Reference 6 is "Roberts E, Fitten LJ: Serum steroid levels in two old men with Alzheimer's disease (AD) before, during and after oral administration of dehydroepiandrosterone (DHEA). Pregnenolone may become rate-limiting in aging, in *The Biological Role of Dehydroepiandrosterone (DHEA)*. Edited by Kalimi M, Regelson W. Berlin, de Gruyter, 1990, pp 43-63." Reference 7 is "Flood JF, Morley JE, Roberts E: Memory enhancing effects in male mice of pregnenolone and steroids metabolically derived from it. *Proc Natl Acad Sci USA* 1992; 89:1567-1571." Also, please note that Eugene Roberts, Ph.D., is from Duarte, Calif.

In the letter "Addition of Fluoxetine to Clozapine" by Shawn L. Cassady, M.D., and Gunvant K. Thaker, M.D. (September 1992, p. 1274), the phrasing in the fifth line of the first paragraph should read "concomitant use of clozapine and fluoxetine."

The Listening Healer in the History of Psychological Healing

Stanley W. Jackson, M.D.

***Objective:** The purpose of this paper is the assessment of the healer's listening as an aspect of the history of caring and curing, with particular attention to its place in psychological healing. **Method:** An extensive range of philosophical, religious, and medical sources from antiquity to the present were studied. **Results:** Over the centuries, listening has been a crucial aspect of the various endeavors undertaken by healers in the interest of acquiring information from, achieving understanding of, and bringing about healing effects for sufferers. Yet it has been vision rather than hearing that has been emphasized in knowing and understanding, and looking rather than listening that has been emphasized in healing endeavors. Only around the turn of the twentieth century did there emerge the focused study of care in listening, of listening beyond the words themselves, and of the significance of the interested listener as a soothing, empathic force. **Conclusions:** The place of listening in depth and with empathy is a crucial element in healing. While the emphasis on looking remains significant in the gathering and appraisal of data, at times it threatens to overwhelm the need for an attentive and concerned listener. There appears to be a natural tension between the two modes that has, in modern times, been translated into a tension between a scientific mode of gaining information and a humanistic mode of knowing sufferers. A healer neglects either one at his or her peril—and at the peril of his or her patients.*

(Am J Psychiatry 1992; 149:1623–1632)

I should first note that the term “psychological healing” is used to denote a broad range of mental, psychic, or psychological interventions that have served healing, or at least ameliorative, purposes over the centuries. The array of twentieth-century psychotherapeutic interventions would be subsumed as species within this genus, along with many other psychological interventions, new and old.

Among other things, a healer is commonly a person

to whom a sufferer tells things; and, out of his or her listening, the healer develops the basis for therapeutic interventions. The psychological healer, in particular, is one who listens in order to learn and to understand; and, from the fruits of this listening, he or she develops the basis for reassuring, advising, consoling, comforting, interpreting, explaining, or otherwise intervening.

One author—an authority on communication—has said: “To be human is to speak. To be abundantly human is to speak freely and fully. The converse of this is a profound truth, also: that the good listener is the best physician for those who are ill in thought and feeling” (1).

Another authority—a psychological healer *par excellence*, the late Frieda Fromm-Reichmann—termed listening “a basic psychotherapeutic instrumentality.” She said that, if she were asked to state in one sentence what were “the basic requirements as to the personality

Presented as the Benjamin Rush Award Lecture at the 144th annual meeting of the American Psychiatric Association, New Orleans, May 11–16, 1991. Received Aug. 19, 1991; revision received Feb. 26, 1992; accepted March 19, 1992. From the Department of Psychiatry and the Section of the History of Medicine, Yale University School of Medicine. Address reprint requests to Dr. Jackson, Rm. L218, Yale University School of Medicine, 333 Cedar St., New Haven, CT 06510. Copyright © 1992 American Psychiatric Association.

and the professional abilities of a psychiatrist," she would reply, "the psychotherapist must be able to listen." For her, this meant "to be able to listen and to gather information from another person in this other person's own right, without reacting along the lines of one's own problems or experiences" (2).

SEEING AND HEARING IN KNOWING AND UNDERSTANDING

Visualism has held a primary position in the history of thought. Both the emphasis on direct visual referents and the predominant use of visual metaphors in the history of man's thinking about reality and experience were reflections of a primary emphasis on vision in studying natural phenomena and in developing explanations for how man knows things. This emphasis on vision was a central theme in classical Greek philosophical thought: In large measure, what these Greek thinkers knew was what they had seen. As the five senses were gradually differentiated from one another as sources of information, seeing was accorded the predominant position in the acquisition of knowledge. From "insight" to "enlightenment," and beyond, our language continues to be replete with visual metaphors in the language of knowing (3). Associated with this emphasis on vision was a relative inattention to hearing, and this was even more the case with the other external senses. As Aristotle (384–322 B.C.) stated it in his *Metaphysics* (4),

All men by nature desire to know. An indication of this is the delight we take in our senses . . . above all others the sense of sight . . . The reason is that this, most of all the senses, makes us know and brings to light many differences between things.

In his *Sense and Sensibilia*, he referred to "smelling, hearing, seeing" as senses that, to those animals that possess them, "are a means of preservation . . . But in animals which have also intelligence they serve for the attainment of a higher perfection." He then gave special attention to seeing and hearing. As he had in his *Metaphysics*, he emphasized that "seeing . . . is in its own right the superior sense"; but he added, "for developing thought hearing incidentally takes the precedence." He went on to say that "it is hearing that contributes most to the growth of intelligence" (5); and, in *On the Soul*, he commented to the effect that hearing was necessary and crucial for the receiving of communication (6). Hearing continued to be accorded a special place as the sense that, by receiving speech, "mediated between minds"; and, through hearing, sound "as music" had "emotional quality" and could "be made a factor in the formation of the soul" (7). Still, though, seeing continued to be predominant in discussions of sensation and perception and to be emphasized in considerations of how knowledge was acquired. "In fact, throughout the Middle Ages, there was a tendency to ignore the other

senses and concentrate on vision, while expressing the conviction that the general principles applying to vision should also hold true for the other senses" (8).

THE LISTENING HEALER

In most of the recognized modes of psychological healing over the centuries, it is clear that the would-be healer, in some way or other, has taken some pains to learn about the sufferer's ailments or difficulties in the process of developing a basis for his or her healing efforts. Sometimes the sufferer has presented himself and his difficulties to the healer who has mainly listened and, in so doing, has acquired the data needed in order to plan a helpful endeavor. Often enough, the listening has been supplemented by questions to bring out further data. Sometimes data have been conveyed to the healer by family members or friends of the sufferer, whether by word of mouth or by correspondence. Again and again, talking has clearly been an important aspect of the sufferer's activity in informing the healer about his ailments and difficulties and in the ongoing interaction with the healer as a healing process has taken place. And so, complementarily, the healer's listening has been a crucial element as well.

These matters are obvious enough in examining historical materials about the distresses and ailments of sufferers and about the psychological healing endeavors undertaken in response to them, but it is almost totally by inference that this can be said. Very little is said about the listening aspect of these encounters and processes. It seems to have been quite taken for granted in the written accounts left to us.

Then the significance of listening can be inferred from another type of evidence, more obvious, albeit still somewhat indirect. This evidence comes from repeated indications to the effect that the troubled and the suffering have yearned for an interested and concerned listener. Particularly poignant instances of this yearning for a listener who cares are found in the Bible, in *The Book of Psalms*, where particular Psalms and their place over many centuries make it clear that listening has been viewed by many as having the potential to ease a person's distress and suffering: "Hear my prayer, O Lord, and let my cry come unto thee . . . incline thine ear unto me" (Psalm 102). "Lord, hear my voice: let thine ears be attentive to the voice of my supplications" (Psalm 130). "Lord, I cry unto thee: make haste unto me; give ear unto my voice, when I cry unto thee" (Psalm 141). "Attend unto my cry; for I am brought very low" (Psalm 142). Recognizing this need for someone to listen with nurturant attentiveness, Fleischman has aptly referred to "a God of listening" in discussing these yearnings. And he grouped such yearnings with "the need to be seen, known, responded to, confirmed, appreciated, cared for, mirrored, recognized, identified," as "the yearning for witnessed significance" (9). Further, this theme of the wished-for listener is an inherent aspect of the practice of prayer.

The significance of the listener is repeatedly present, albeit implicitly, in the long traditions of various psychological healing activities—such as consolation, persuasion, confession, or confiding—each of these being a long-established mode of ministering psychologically to distressed and troubled persons and of bringing healing relief. And, here and there, there are clear indications of distress in the face of a listener's inattention or unsatisfactory listening. For the most part, though, listening seems to have been taken for granted; and the predominant emphasis continued to be on seeing or looking as the means of obtaining information about and coming to understand suffering persons.

THE NINETEENTH CENTURY

The nineteenth century brought even further emphasis on seeing rather than hearing, on looking rather than listening, in the realms of sickness and healing. In the sufferer's appearance, in his visible behavior, there had always been thought to be evidence to aid the healer in understanding the sufferer's illness and to guide him toward appropriate treatment and accurate prognosis. Then, with the nineteenth century's accumulating populations of mentally ill persons who came under the observation of alienists and psychiatrists, a new tradition of seeing and looking developed which argued that significant correlations were there to be observed between the sufferer's appearance and his psychopathology. Physiognomy, or the study of human character through facial configuration, had long been considered a meaningful enterprise; and it had been specially furthered in the eighteenth century by the work of Johann Kaspar Lavater (1741–1801). Then, in the nineteenth century, Franz Joseph Gall (1758–1828) and Johann Kaspar Spurzheim (1776–1832) evolved the discipline of phrenology in which the bumps and contours of the head were thought to give evidence of mental faculties and character traits.

Against this background, Alexander Morison (1779–1866) presented his *Outlines of Lectures on Mental Diseases* in which he addressed the physiognomy of the insane and to which he added illustrative engravings; and, in 1838, he published *The Physiognomy of Mental Diseases* with over 100 plates of psychiatric patients aimed at demonstrating pictorially observable correlates of their mental illnesses. J.E.D. Esquirol (1772–1840) used illustrations of patients in his textbook, *Maladies Mentales*, in 1838. And, in the late nineteenth century, Jean-Martin Charcot (1825–1893) and Paul Richer (1849–1933) published extensively on correlations between appearances and psychopathological states. Within this context, in the 1850s, Hugh W. Diamond (1809–1886), a psychiatrist who succeeded Morison at the Surrey County Asylum, developed the work that was to earn him the title of “the father of psychiatric photography.” Among the uses he made of his photographs of the insane, a primary one was the photograph as a diagnostic tool with insane patients,

based on correlations of physiognomy and clinical states (10).

Out of these activities and their associated assumptions, there emerged a groundswell of support for the notion that looking at insane patients was the essential avenue to knowledge of their psychopathology. Attention to the shape of the face and the head, to the facial expression, to gestures and postures, and to body build was thought to be of central significance. The primacy of seeing in knowing had received new support.

It is well to be reminded that these trends in looking in order to know about the mentally ill evolved in an era in regard to which Michel Foucault (1926–1984) could refer to the new clinical medicine as essentially emerging out of an emphasis on seeing. In his *Birth of the Clinic*, he stated that “this book . . . is about the act of seeing, the gaze” (11). He went on to discuss “the clinical gaze” at some length and gave it a crucial place in the acquisition of clinical knowledge. By the end of the nineteenth century, the primacy of visual observation in medical knowledge in general was rarely questioned. It was against this background that listening gradually came to be attended to by healers in ways that it never had before.

“THE TALKING CURE” AND LISTENING

In the famous case of Anna O., the patient who was treated by Josef Breuer (1842–1925) in the early 1880s and whose treatment was so influential in the early development of the work of Sigmund Freud (1856–1939), the patient referred to the treatment as a “talking cure,” and Breuer used such phrases as “talked through,” “talked away,” and “talking out” to indicate the nature of the therapeutic activity (12). For all the emphasis on the patient's talking, though, it is consistently clear that the physician's role was also crucial and that his listening was a critical feature of that role. In reading about this clinical work, one takes the listening for granted, and it is clearly reasonable to do so. But it was only later, when thoughtful students of the Anna O. case were subjecting it to intensive study, that this theme of listening came to be made explicit. For example, Ellenberger aptly referred to “the tranquillising effect of Breuer's listening to the stories she told him” and observed that “he was able to soothe her by listening to her stories” (13, pp. 275–276). The emphasis on the therapeutic value of talking had always implied a meaningful listening as a complementary activity, but Ellenberger was identifying the further element of the soothing and healing effect of the listener's interested listening.

Years later, with his own development of psychoanalysis well advanced, Freud had something to say about listening. In his “Recommendations to Physicians Practising Psycho-Analysis,” he urged that the psychoanalyst not direct his “attention to anything in particular” and that he maintain “the same ‘evenly-suspended attention’ . . . in the face of all that one hears”

(14, pp. 111–112). In that essay he was advising against various determined efforts to remember and was urging an unbiased, open-minded listening to everything the patient had to say. He explicitly indicated that the psychoanalyst would thus remember more and with less intrusion of bias; and he implicitly indicated that such a way of listening would lead to the psychoanalyst hearing more. Freud said little else about the subject of listening, but this advice has influenced the manner of listening for many a clinician since that time. In fact, these recommendations of Freud's became central in considerations of listening in the teaching of psychoanalytic technique over many decades. (An effective and representative summary of how the analyst listens was provided by Ralph Greenson [15].) As Ricoeur was to state it later, "corresponding to the 'total communication' on the part of the patient is the 'total listening' on the part of the analyst" (16).

Theodor Reik (1888–1969) particularly emphasized this special approach to listening, though he preferred the term "free-floating attention" rather than "evenly-suspended attention." But Reik's considerations of the listening healer went much further, and he offered some profound observations on the subject in his book on "the inner experience of a psychoanalyst," *Listening with the Third Ear*. Borrowing the term "the third ear" from Nietzsche, Reik used this title phrase to refer to a capacity that he thought that a psychoanalyst needed to develop. The psychoanalyst needed "to learn how one mind speaks to another beyond words and in silence. He must learn to listen 'with the third ear.' " This "third ear . . . can catch what other people do not say, but only feel and think; and it can also be turned inward. It can hear voices from within the self that are otherwise not audible because they are drowned out by the noises of our conscious thought-processes." Reik was discussing the notion of the analyst sensing and resonating to feelings and listening for nuances and meanings that went beyond, or lay beneath, the spoken words. These references to listening meant a sensitive, discerning use of the sense of hearing, but he was also using listening to stand for all the senses. The analyst was urged to open "all his senses to these impressions" (17). In his silence the analyst was to provide a receptivity that was freeing to the patient and that thus facilitated a more profound communication from sufferer to healer.

EMPATHIC LISTENING

Empathic listening is a significant feature of modern thought on listening in healing contexts, but the term is a relative newcomer in the language of psychological healing. In order to appreciate how it has emerged, though, one has to consider the history of the parent term "empathy." The roots of the latter term are to be found in the thinking of Theodore Lipps (1851–1914) and his term *Einfühlung*. In 1872 Robert Vischer (1847–1933) addressed the question of an observer at-

tributing feeling and emotion to works of art and to forms of nature. He explained this in terms of some unconscious process in the observer endowing such objects with vital content. And he named it *Einfühlung*. Then, beginning in the 1890s, Lipps studied this extensively and effectively established the term *Einfühlung* for continued use. His original view belonged in the realm of esthetics and dealt with the attribution to or projection into an art object of a viewer's feelings (18). As Lipps defined it at one point, *Einfühlung* meant "feeling something, namely, oneself, into the esthetic object" (19, p. 302). Later, he came to include one person's appreciation of the feelings and attitudes of another person as one of the ways in which *Einfühlung* might be manifested (20, p. 184). The English term "empathy," with the meaning of "feeling into," became the accepted translation for *Einfühlung* after being suggested by Edward B. Titchener (1867–1927) in 1909 (21, p. 21).

There were various streams of development out of these origins, both in theory and in practice. But it was only slowly that the notion of empathy entered the clinical realm. Sigmund Freud was interested in Lipps's work and made several uses of the latter's concept of *Einfühlung* in his *Jokes and Their Relation to the Unconscious* in 1905. Although these were not clinical applications of the concept, some of them did entail "putting oneself into" the psychical state of another person, the one producing the witticism (22). Then, although it entailed empathy with a fictional person, a similar projection of oneself into the psychical state of another was mentioned in *Delusions and Dreams in Jensen's Gradiva* in 1907 (23). Perhaps more interesting to the clinician was Freud's use of the concept in his *Group Psychology and the Analysis of the Ego* in 1921. He referred to "the process which psychology calls 'empathy (*Einfühlung*)' and which plays the largest part in our understanding of what is inherently foreign to our ego in other people"; and he invoked it to explain group members' appreciation or understanding of one another. In his brief discussion he associated empathy with identification and with imitation, stating, "a path leads from identification by way of imitation to empathy, that is, to the comprehension of the means by which we are enabled to take up any attitude at all towards another mental life" (24). (Basch [25, p. 103] has urged a significant correction to this translation. Rather than empathy enabling us "to take up any attitude at all towards another mental life," he points out that the implication was that "empathy was indispensable when it came to taking a position regarding another person's mental life".) Although not a clinical application of the concept, it was a use that seems to have had implications for clinical contexts.

The first study in the psychoanalytic literature to address empathy explicitly as a factor in the clinical process seems to have been "The Psycho-Analytic Method of Observation" by Theodore Schroeder (1864–1953) in 1925. Focusing on "*empathic insight; empathic understanding; retrospective and inductive introspec-*

tion," Schroeder wrote, "the psycho-analytic method makes experimental use of empathy as a means of reading something out of the psyche of another." For the psychoanalyst or "empathist," this "empathic viewing of another's psyche involves a maximum of attention upon the associated affective tones, values and processes." He went on to say that "empathic insight implies a seeing (re-living) as if from within the person who is being observed. It is as if, by a conscious withdrawal of interest and by the exclusion from consciousness of all present relationship to everything else, one places one's own consciousness at the disposal of the unconscious determinants of another's personality" (26, pp. 159, 162). Surprisingly, from Deutsch and Ferenczi to Kohut and since, the psychoanalysts who have written about empathy have said nothing about Schroeder's paper.

In 1926, Helene Deutsch (1884–1982) briefly discussed "intuitive empathy" in clarifying the nature of seemingly occult events in psychoanalysis; and she did so in a way that took it for granted that it was not an unusual phenomenon in the psychoanalytic process (27, pp. 136–137). It is Sandor Ferenczi (1873–1933), though, who is usually thought to have been the first psychoanalyst to suggest explicitly that empathy is, and should be, an element in clinical work. In 1928, in "The Elasticity of Psycho-Analytic Technique," he introduced the notion of *tact* as a crucial factor in determining when the analyst should undertake an intervention, particularly an interpretation. He then raised the question, "But what is 'tact'?" and he answered, "It is the capacity for empathy." He then elaborated to the effect that, through empathy, having "succeeded in forming a picture of possible or probable associations of the patient's of which he is still completely unaware, we, not having the patient's resistances to contend with, are able to conjecture, not only his withheld thoughts, but trends of his of which he is unconscious." He went on to say that "this empathy will protect us from unnecessarily stimulating the patient's resistance, or doing so at the wrong moment." Further, the analyst's empathy served to protect the patient from unnecessary pain. He used the term "the empathy rule" for shorthand reference to these matters. He noted that the analyst's mind "swings continuously between empathy, self-observation, and making judgments." And he concluded by saying, "My principle aim in writing this paper was precisely to rob 'tact' of its mystical character" (28).

After Ferenczi, empathy was only rarely mentioned in the psychoanalytic literature over the next 25 years (29, 30). Then, in the 1950s, significant references to it began to increase (31–36). The situation prior to this is stated well by Roy Schafer, a significant contributor to the 1950s attention to empathy. "Comparatively little investigation and conceptualization of empathy can be found in the psychoanalytic literature; despite persistent emphasis on its importance in the therapeutic process, not to speak of child development and personal relationships" (35). Particularly influential among the 1950s contributors was Heinz Kohut (1913–1981),

whose work was to lead to the self psychology of today and whose emphasis on the role of empathy influenced psychoanalysis and psychotherapy in ways that brought empathy into the center of their clinical considerations (34). Then there was the work of Ralph R. Greenson (1911–1979), another member of this 1950s group, who wrote on "Empathy and Its Vicissitudes."

Most experienced psycho-analysts will agree that in order to carry out effective psychotherapy a knowledge of psycho-analytic theory and the intellectual understanding of a patient is not sufficient. In order to help, one has to know a patient differently—emotionally. One cannot truly grasp subtle and complicated feelings of people except by this 'emotional knowing.' It is 'emotional knowing,' the experiencing of another's feelings, that is meant by the term empathy. It is a very special mode of perceiving. Particularly for therapy, the capacity for empathy is an essential prerequisite. Although I believe these points are well known it is striking how little psycho-analytic literature exists on the subject of empathy . . . There seems to be a tendency among analysts either to take empathy for granted or to underestimate it (36).

It must be much more than a coincidence that Schafer, Kohut, and Greenson, apparently working quite independently of one another, came out with such vigorous espousals of the importance of empathy within a very short span of time. Individually and collectively, they have had a significant influence on psychoanalysis and psychotherapy in the 30 years since then; and empathy has become a common topic in the literatures of those disciplines.

Although often unacknowledged in the psychoanalytic and psychotherapeutic literatures, there were other scholarly traditions in which respectful attention was being paid to notions akin to empathy as ways of appreciating and knowing about the inner life of another person. As early as the beginning of the 1920s, social psychologists and sociologists were developing such ideas and studying their place in interhuman relationships. I would mention particularly Charles H. Cooley (1864–1929) and his "sympathetic introspection" (37) and George H. Mead (1863–1931) and his "role-taking" (38).

Turning again to clinical contexts, by 1951, when his *Client-Centered Therapy* was published, Carl R. Rogers' psychotherapeutic approach had come to have empathy as a recognized central element in its operations.

It is the counselor's function to assume, in so far as he is able, the internal frame of reference of the client, to perceive the world as the client sees it, to perceive the client as he is seen by himself, to lay aside all perceptions from the external frame of reference while doing so, and to communicate something of this empathic understanding to the client (39).

During the 1940s, Rogers had gradually developed this viewpoint, and it became the essence of what, in his clinical work, he meant by "client-centeredness."

These various notions of empathy vary somewhat in their details and in how they are used. But, whatever is

the case in a particular viewpoint, they all entail a coming to know about another through an imaginative experience of being in the world of his or her thoughts, feelings, and attitudes. One way or another, what is involved is a profound listening. The healer truly *hearkens* to the sufferer—that is to say, the effort is to hear *and* to know or understand.

While it has always been clear in the psychoanalytic literature that empathy entailed attentive listening to the patient, it was only after the increased, more focused attention to empathy in the 1950s that explicit references to listening became more frequent and even consistent. Greenson emphasized listening as a matter of course, but then made the point that “listening from the ‘outside’ ” was insufficient and that it had been crucial that he “shifted—from listening and observing from the outside to listening and feeling from the inside,” i.e., from an empathically attuned position (36).

Gradually, out of the self psychologists’ attention to empathy and the unavoidable, although often unstated, significance of the analyst’s listening, there emerged an increasingly explicit emphasis on psychoanalytic listening and on empathic listening in psychoanalysis and psychotherapy. Although clearly indebted to and influenced by Kohut in her attention to empathy and in her mode of practice, Evelynne Schwaber seems to have been crucial in bringing about these newer terminological practices. In a series of papers from 1979 to 1983, she discussed empathy as “a mode of analytic listening” and as “the listening perspective,” in relation to self psychology (40–42). She wrote about being used “as part of the core of the patient’s self” by a pathologically narcissistic patient and then went on to say

I slowly came to recognize that listening in this way—having to place myself inside the patient’s self experience—called somehow for another mode of listening, of perceiving, than one in which I would be positioned somewhat ‘outside’—that is, as target rather than subject of the patient’s affects, drives, and defenses (41).

Adding that “it is this listening stance which is what I mean by empathy,” she referred to empathy as “a specific, scientific mode of perceiving—the matrix of depth-psychological observation.” This “quality of listening,” this “subjective listening mode,” was “the empathic mode,” a “mode of psychological data gathering” (41). Schwaber argued that “each theoretical system may suggest a definition of the listening stance within its own framework,” but that, as a method of gathering data, empathy has a certain independence of theories. This listening mode or “listening stance attempts to minimize the introduction of an ‘outsider’ view.” She termed this listening stance “empathic listening” (40). Parenthetically, it should be noted that listening is certainly at the heart of the matter in *empathic listening*, and yet the use of the term “listening” in such contexts is partly an effort to capture metaphorically a very complicated process.

Already well attuned to the significance of listening

in psychotherapy, more recently Chessick has taken up the theme of empathic listening in a thoughtful and useful way. In his textbook of psychotherapy in 1974, he said that “it is clear . . . that listening, in a therapeutic sense, is an extremely active process. It occurs silently within the therapist and permits him fully to observe the patient’s behavior, as well as his own association and emotional responses to the material presented by the patient” (43). Then, in his recent book on listening in psychotherapy, listening is the central, organizing theme in a study of five different “listening stances” that might be assumed by a psychotherapist; and he addresses empathic listening in some detail. Noting that Schwaber’s approach introduces “an alternative mode of psychoanalytic listening from that of Freud,” he categorizes her “point of view as belonging to only one of the five models of theoretical understanding that must be used in a comprehensive listening process” (44).

DISCUSSION

Toward Listening

In the realm of psychological healing, the twentieth century has seen an increasing recognition of the significance of the healer’s listening in the healing process. And there are many indications of such a trend other than those just cited from psychoanalytic and psychodynamic therapeutic traditions. Turning to the context of a general physician’s consultation room, attentive, interested listening can turn an inchoate litany of complaints into a gradually coherent story of distress and discomfort. The patient is the better for having told the doctor, whether it has been a confessing, a confiding, a catharsis, or a revealing of physical symptoms that would have otherwise gone undetected; and the doctor is the better for having been *with* the patient in a healing endeavor rather than having rapidly gotten rid of him with the aid of a prescription pad. Often enough, the physician’s listening has allowed the emergence of more private concerns and symptoms that have been the issues that were more crucially in need of therapeutic attention.

Or, I can turn to an example from a medical student’s experience. This is a painful example of how a clinician struggled through a patient’s off-putting distress to listen in a deeply meaningful, and useful, way. I quote from Kleinman’s *Illness Narratives*.

The . . . patient was a pathetic seven-year-old girl who had been badly burned over most of her body. She had to undergo a daily ordeal of a whirlpool bath during which the burnt flesh was tweezed away from her raw, open wounds. This experience was horribly painful to her. She screamed and moaned and begged the medical team, whose efforts she stubbornly fought off, not to hurt her anymore. My job as a neophyte clinical student was to hold her uninjured hand, as much to reassure and calm her as to enable the surgical resident to quickly pull away the dead, infected tissue in the pool of swirling water, which rapidly turned

pinkish, then bloody red . . . I tried to distract this little patient from her traumatic daily confrontation with terrible pain. I tried talking to her about her home, her family, her school—almost anything that might draw her vigilant attention away from her suffering. I could barely tolerate the daily horror . . . Then one day, I made contact . . . uncertain what to do besides clutching the small hand, and in despair over her unrelenting anguish, I found myself asking her to tell me how she tolerated it, what the feeling was like of being so badly burned and having to experience the awful surgical ritual, day after day after day. She stopped, quite surprised, and looked at me from a face so disfigured it was difficult to read the expression; then in terms direct and simple, she told me. While she spoke, she grasped my hand harder and neither screamed nor fought off the surgeon or the nurse. Each day from then on, her trust established, she tried to give me a feeling of what she was experiencing. By the time my training took me off this rehabilitation unit, the little burned patient seemed noticeably better able to tolerate the debridement (45).

I would now like to consider briefly some of the generic ingredients that go to make up these various instances of invaluable listening. The effective healer in the realm of psychological healing tends to be someone who is interested in talking with and listening to the other person. And these inclinations are grounded in an interest in other people and a curiosity about them. Further, such healers have a capacity for caring about and being concerned about others, particularly about those who are ill, troubled, or distressed. The sufferer—ill, troubled, or distressed—tends to be someone who seeks out a healer who will be interested, concerned, and responsive to his distress, who will minister to his ailments, and who will bring him relief, if not cure. He seeks to be listened to, to be taken seriously, and to be understood, as crucial aspects of this process.

All this, in turn, is set in a context of human need for connection with other persons, for the intimacy of a relationship with another person, for relationships as antidotes to aloneness or being isolated, for the closeness or meaningfulness associated with such connections (quite distinct from a sexual relationship or an erotic attachment). And these needs for such relationships influence both sufferers and healers. For the sufferer there is a yearning to be listened to, to be valued, and to be understood. And the healer has his own need to listen, to understand, and so to bridge the divide between the two persons in the potentially healing dyadic relationship.

In situations such as these, the attentive listening of a concerned and interested healer can, and often does, have a compelling effect on the sufferer. The sufferer, often enough, responds by telling more about himself, by revealing more. The very process of the sufferer's confiding, in turn, commonly has a compelling effect on the listening healer. The listening and the talking, the talking and the listening, have a mutual attachment effect. The relationship is deepened—more is said, more is heard, more is understood, more of a sense of being understood is experienced. The term "the talking cure" is not without its relevance to such situations, but, at

best, the term is incomplete. The healer's listening is just as crucial; in fact, it is essential. While this listening must entail attentiveness and interest, the healer as listener is at the heart of the matter. The term "the listening cure" would be just as relevant. The sense that you have been listening, that you have tried to appreciate the sufferer's distress or dilemma, that you are concerned and have tried to understand, that your listening may have led to understanding, these things matter profoundly to a sufferer. They may help you toward a healing intervention, and they may help themselves even be healing in their effects. Perhaps we should say "the talking *and* listening cure."

Interferences With Listening

For all the increased recognition of the value of listening, there is, too often, an anxiety in the face of listening—perhaps I should say a fear of what might be heard and its disturbing, distressing effect on us as listeners. What we will hear, if we allow ourselves to listen, will be so disturbing, so terrible—be it about severe pain, about distress in the face of disabling disease, about panic, about the terror of inner disintegrative trends in a psychosis, or about horrible rememberings or relivings of past traumata. Or there might be some other communication that would stir disturbing feelings in a healer—anger, shame, guilt, sexual feelings. These moments in the sufferer-healer interaction can interfere mightily in listening to a sufferer, in learning about his difficulties, in coming to appreciate and understand those difficulties. These sorts of effects can block listening that could be essential to acquiring the understanding necessary to treat the sufferer reasonably well. They can preclude the use of the healer's empathic capacities that might be essential to learning about the sufferer's difficulties and providing the necessary healing interventions. They can influence healers to interrupt, to change the subject, to talk instead of listening, to keep away somehow from such troubling effects.

Useful, even essential, listening may be avoided by modern healers for other reasons, though. Sometimes explained in terms of the efficient use of a healer's time, sometimes determined by the intrusions of modern diagnostic technology, and sometimes accounted for by strivings to be scientific or at least objective, modern clinicians have often distanced themselves from patients, or have been distanced by a clinical structure, in ways that have seriously interfered with the valuable clinical listening that the twentieth century has come to appreciate. While anxiety or fear in the face of disturbing communications may be hidden within these other rationales, the latter do seem to be distinct interferences in their own right.

In a thoughtful history of doctor-patient relationships entitled *Bedside Manners*, Shorter takes some pains to demonstrate "the informal psychotherapeutic power of the consultation," which power he attributes to "the catharsis that the patient derives from telling his story to someone he trusts as a 'healer.'" Unfortu-

nately, as Shorter points out, the recent trend in medicine has been "to steer the consultation toward a single, identifiable physical problem, the 'chief complaint.'" Physicians have developed question-and-answer techniques in history-taking that move patients toward a chief complaint, a recognizable pattern of symptoms, and then to a basis for a prescription. Often enough, this process discovers a plausible excuse for the medical visit, while the real cause of the visit remains undiscovered. It seems that what has occurred is a shift from being patient-oriented to being disease-oriented. By reducing the opportunity for the patient to talk and avoiding the need for the doctor to listen, a type of efficiency has been achieved, but the cost has included the loss of healing opportunities, opportunities for psychological healing in the medical consultation itself. "The erosion of careful listening" has often meant the loss for patients of the "opportunity to say what is really troubling them" and of "the cathartic value of telling" their stories. Shorter points out that "listening is the main kind of informal psychotherapy the family doctor is able to conduct," that listening is a crucial ally for the doctor in helping his patients cope with psychological distress and mental disorders (46).

As previously suggested, there are still other ways in which the significance of listening is often lost sight of in contexts of sickness and healing. We are in an era of remarkable, almost incredible, advances in molecular biology in psychiatry—in medicine, in general. And various technological advances have allowed us to learn remarkable new things from patients that can guide our treatments. Yet these same technologies can also serve to distance us from patients. While seeing more, we are often at high risk of hearing less. From X-rays to modern imaging techniques, there is a comforting concreteness, a reassuring reliance on what can be seen. The readings derived from laboratory tests, too, so often provide a reassuring sense of visualizable certainty in the numbers on the page of a report. What the sufferer tells the healer is not viewed as being without significance, but, all too often, it quickly moves the healer toward a category of things to check out with his technologies and, sooner or later, to a category of concrete, material interventions: substances or procedures. The healer has listened in his special ways, but, all too often, has heard mainly through the filters provided by his categories of investigative procedures, his diagnoses, and his technologically based interventions. And somehow the sufferer has been put at a distance. The healer may listen more in narrowly categorized ways, and yet he will hear less and is in serious danger of attending less to the person. As Spiro has stated, "the physician looks for disease rather than listens to the patient. Yet illness, the patient's complaint, can only be understood by listening to what he says." Although the detection of disease may come from the image, "the diagnosis of illness comes from listening." "Listening is much harder work than seeing; it takes time, concentration, and active participation. But physicians need to listen as much as to look, to make all senses work together" (47).

CONCLUSIONS

There has been surprisingly little emphasis on the value and significance of clinical listening over the centuries. Even further, with the gradual emergence of modern clinical medicine in the nineteenth century, it was clinical looking, above all, that brought the most valued information for healers. The visual scrutiny of lesions and of the reflections of disordered function was considered significant above all other sources of data. The growing knowledge of pathological anatomy, both pre-mortem and post-mortem, supported this trend. The development of microscopy, associated staining techniques, and the fruits of the germ theory of disease all served to extend this trend. And, in keeping with what was happening in general medicine, it was thought that what the healer could see in the sufferer from mental illness was the royal road to knowing about that category of sickness as well.

Somehow, though, around the turn of the twentieth century, there was a reaction to all this, an emerging concern with listening to the sufferer. In psychoanalysis and other depth psychologies, what the sufferer could and would tell the healer, the need to facilitate such telling, the need to listen carefully, and the emerging emphasis on empathy as a listening stance were aspects of an increased sensitivity to the person of the sufferer rather than to the disease from which he suffered. Parallel developments in general medicine in the first several decades produced increased concerns about sufferers that were reflected in catch phrases such as "the doctor-patient relationship" and "the patient as a person"; and listening carefully to their patients was urged on physicians as it had never been before. As William Osler put it, "Listen to the patient; he is telling you the diagnosis" (attributed to William Osler, but exact source not identified).

The early twentieth century also saw imaging enter the medical field. With the X-ray, a special type of looking was born. Diagnostic efforts were greatly strengthened. And, at the same time as listening was being increasingly advocated, a more penetrating form of looking was influencing many physicians to rely less on listening. On the one hand, it became common to urge physicians to take time with patients, to allow patients to tell their stories, and to listen to them carefully. On the other hand, all too often physicians perceived themselves as being very busy and heavily burdened, and they took steps to streamline their practices and to save time. Questionnaire approaches to history-taking were introduced; and, sometimes, the taking of a case history was delegated to a nurse or other assistant. Increasing reliance on laboratory tests seemed to make listening even less significant. And the more recent advent of even more powerful imaging techniques took this trend even further.

The same century that has brought more concern with and attention to listening than ever before has introduced more interferences with and rationales for not attending to listening than ever before. Often enough,

patients complain that physicians are too busy, that they are not interested, or that they do not listen. As physicians strive to gather more data, to see more, to be more objective, to be more scientific, they are often experienced by their patients as not listening.

Around the beginning of the century, a growing tension was emerging between medical science and clinical medicine. Encouraged and emboldened by the scientific developments of the latter half of the nineteenth century, medical scientists were arguing for and acquiring a larger place in the medical world, including more respect, positions and departments in medical schools, and an increased influence on what was done therapeutically. As these important changes were occurring, a special dilemma was coming into focus to a degree that it never had before—to attend to the disease or to the sufferer? to treat the disease or to treat the patient? And our century has seen frequent oscillations between concerns about the science of the disease and the humanity of the patient.

Is it that there is, and always will be, a natural tension between looking and listening as ways of knowing? Or is it more a reflection of the tension between a scientific mode of gaining information and a humanistic mode of knowing the sufferers? Whichever it might be, there does now seem to be a well-established tension between attention to diseases and attention to suffering persons.

Speaking to the psychological healer, I would want to remind him or her that the healer who really listens will hear the dejection and sadness that is so often at the heart of anger, the anger so often enmeshed in dejection and despair, the fear so often at the root of hostility, the strength in weakness and the weakness in strength, the more deeply felt in the apparently more prominently felt. To physicians in general, I would ask, "How many of today's complaints about doctors stem from doctors not listening?" Listening is central to learning about and coming to understand a sufferer, and those steps are crucial to being a healer. The healer learns about the sufferer in direct proportion to the quantity and quality of his listening. And this is not to ignore looking, or to overlook disease, or to downgrade objectivity.

In closing, and with apologies to the author of *Ecclesiastes*, "To everything there is a season." A time to speak, and a time to hearken; a time to look, and a time to listen.

Clinical and Research Implications of the Diagnosis of Dysphoric or Mixed Mania or Hypomania

Susan L. McElroy, M.D., Paul E. Keck, Jr., M.D., Harrison G. Pope, Jr., M.D., James I. Hudson, M.D., Gianni L. Faedda, M.D., and Alan C. Swann, M.D.

Objective: The authors reviewed available evidence regarding the status of dysphoric or mixed mania as a distinct clinical state and formulated operational criteria for its diagnosis. **Method:** Studies of dysphoric mania or hypomania in patients with bipolar disorder were analyzed with regard to clinical characteristics, prevalence, demographic features, course of illness, outcome, family history, associated conditions, biological tests, and response to biological treatment. **Results:** Although some studies suggest that dysphoric and nondysphoric mania are similar conditions, others suggest that, compared with nondysphoric mania, dysphoric mania may be more severe; more likely to occur in women; more likely to be associated with suicidality, a younger age at onset, a longer duration of illness, higher rates of personal and familial depression, concomitant alcohol or sedative-hypnotic abuse, neuropsychiatric abnormalities, and poorer outcome; more frequently associated with cortisol nonsuppression; and less likely to respond adequately to lithium but perhaps more likely to respond to ECT or anticonvulsants. **Conclusions:** Substantial evidence suggests that dysphoric mania may be a distinct affective state. Contrary evidence, however, suggests that dysphoric mania may be a form of typical mania, a stage-related or severe form of mania, or a transitional state between mania and depression. Because the evidence may be inconsistent because of varying definitions of dysphoric mania among studies, the authors propose preliminary operational diagnostic criteria for the future study of dysphoric mania.

(Am J Psychiatry 1992; 149:1633-1644)

Mania and depression are often viewed as polar opposites. However, since Emil Kraepelin first described mixed states of manic-depressive insanity (1), it has been known that some patients with acute mania or hypomania simultaneously experience prominent depressive symptoms (1-28). Considerable ambiguity (27) still surrounds this condition, most commonly called dysphoric or mixed mania. For instance, dysphoric mania has been described as a distinct affective

state distinguishable from nondysphoric mania (1, 2, 7-9, 11, 13-26), as a form of typical mania (4, 6, 10), as a stage-related or particularly severe form of mania (5, 24), and as a transitional state between mania and depression (1, 7-9, 11, 12, 29-32). Moreover, the relationship of dysphoric mania to other affective states, such as agitated or mixed depression (32-35), rapid cycling and ultra-rapid cycling (7, 24, 36, 37), delirious mania (3, 4, 15), and the affective lability of borderline personality disorder (38-40), remains unclear.

Undoubtedly, much of the ambiguity surrounding dysphoric mania is due to the lack of widely accepted, empirically based operational diagnostic criteria for the disorder. Although most psychiatric classifications recognize the existence of mixed forms of bipolar disorder, they do not provide separate operational criteria for dysphoric or mixed mania (27), referring instead to different combinations of the criteria for mania and depression and specifying that manic and depressive symptoms either occur together (41), alternate rapidly (42), or occur together and alternate rapidly (43). Thus, DSM-III-R defines bipolar disorder, mixed, by two criteria: 1) current or most recent episode, which involves the "full symptomatic picture of both manic

and major depressive episodes . . . intermixed or rapidly alternating every few days" and 2) prominent depressive symptoms lasting "at least a full day." Only the Vienna Research Criteria (42) provide specific operational diagnostic criteria for stable and unstable "mixed states." However, these criteria stress rapid change or fluctuation between manic and depressive symptoms—and less so the simultaneous occurrence of manic and depressive symptoms—without specifying the time periods within which the changes may occur. Indeed, most diagnostic criteria for mixed bipolar illness—Research Diagnostic Criteria (RDC), *DSM-III-R*, and the Vienna Research Criteria—do not distinguish clearly between dysphoric mania (mania accompanied by depressive symptoms) and ultra-rapid cycling (rapid alternations between mania and depression)—two conditions that may be distinguishable clinically (7, 24).

Given the lack of uniform operational criteria for dysphoric mania, this condition can be defined in broad, intermediate, or narrow terms: 1) mania or hypomania accompanied by any depressive symptom (broad), 2) mania or hypomania accompanied by several depressive symptoms (intermediate), and 3) mania accompanied by full-scale or syndromal major depression (narrow). Of these definitions, the broad one is probably not useful because many patients with acute mania simultaneously display at least some degree of depressed mood (1–4, 6, 10, 22, 24, 27). Therefore, we elected to review studies of dysphoric mania defined according to the intermediate or narrow definitions; we applied these definitions to studies examining dysphoric mania or hypomania, mixed mania, mixed states, and severe mania in patients with bipolar disorder. Studies apparently examining dysphoric mania or hypomania according to our intermediate or narrow definitions were then analyzed with regard to clinical characteristics, prevalence, demographic features, course of illness, outcome, family history, associated conditions, biological tests, and response to biological treatment.

CLINICAL CHARACTERISTICS: CLASSIC AND MODERN STUDIES

In the third century, according to Davidson (44), Aretaeus of Cappadocia observed that although some manic patients were "cheerful and like to play," others were "passionate and destructive." Robertson (45), in 1890, advocated dividing mania into "hilarious" and "furious" types. Kraepelin (1) described six types of mixed states based on different combinations of manic or depressive mood, activity, and thought (27). These states included depressive or anxious mania, excited or agitated depression, mania with poverty of thought, manic stupor, depression with flight of ideas, and inhibited mania. Of these six states, depressive or anxious mania—defined by depressed mood, manic activity, and manic thought—probably most closely resembles the definition of dysphoric mania used in this review.

Kraepelin described these patients as "anxiously despairing," greatly restless with "a wholly senseless pressure of activity," excited, and distractable, with flight of ideas and "ideas of sin and persecution."

Modern studies have generally defined dysphoric or mixed mania as mania accompanied by prominent depressive symptoms (table 1). Although most modern studies used standardized operational diagnostic criteria to define mania (e.g., RDC or *DSM-III*), they varied considerably in their definition of prominent depressive symptoms. For instance, several authors (3, 14, 26, 28) used a narrow definition of dysphoric or mixed mania, requiring that a *full* depressive syndrome co-occur with a full manic syndrome for a certain period of time. Most commonly, an intermediate definition was used, requiring only that several or substantial depressive features be present. The latter was usually determined when the patient achieved a certain score on specific depression rating instruments while acutely manic (e.g., a depression index score on the Manic-State Rating Scale [46] greater than or equal to 5 [6] or 8 [23], a depressive symptom cluster on the Kupfer-Detre System [47] greater than 18 [7–9], or a Hamilton Rating Scale for Depression [48] score greater than 7 [22] or 15 [15–18, 24]). Finally, some authors included mania with mild depression (22) and hypomania with prominent depression (6, 11, 39) as forms of dysphoric mania, and others included major depression with prominent agitation as a mixed bipolar state distinct from mixed mania (32, 35).

Many modern studies provided clinical descriptions of dysphoric mania. Patients were described as displaying a wide range and varied combinations of affective, cognitive, behavioral, and neurovegetative symptoms. Indeed, several authors remarked that the hallmark of dysphoric mania was variability or lability in mood and psychomotor activity (3, 4, 7, 12, 13, 24) or a "pleomorphic" or "chameleon-like" presentation with "innumerable combinations" of often contrasting symptoms (1, 2, 7–9, 26). In a study of 14 episodes of mixed manic-depressive psychosis in 10 patients, Winokur et al. (3) observed depression, euphoria, lability, irritability, distractibility, and greater psychomotor activity in all 14 episodes. Insomnia, pressure of speech, hostility, decreased sexual interest, grandiosity, and disorientation were seen in most episodes; suicidal threats or attempts, flight of ideas, increased alcohol intake, and anxiety attacks were also prominent.

Dysphoric mania appeared to be frequently accompanied by psychotic symptoms (often depressive or mood-incongruent) (1–3, 5, 7–9, 11–14, 20, 26, 28). In general, however, the overall incidence of psychosis did not differ between patients with dysphoric and nondysphoric mania (16, 26). Symptoms seen in delirious mania, such as incoherence and disorientation, were also frequently reported (3, 5, 15). Secunda et al. (15), for instance, found that patients with mixed mania displayed greater degrees of cognitive impairment than patients with nonmixed mania. Several studies suggested that patients with dysphoric mania were

^aBroad=mania or hypomania accompanied by mild depression. Intermediate=mania or hypomania accompanied by prominent depressive symptoms. Narrow=mania or hypomania accompanied by full-scale or syndromal major depression. Stage II=moderately severe mania, characterized predominantly by anger and irritability. Stage III=mania at peak severity, characterized by extreme dysphoria, desperation, severe panic, hopelessness.

^bNumber of patients with acute mania or hypomania studied.

^c63% of all patients with mania were female.

^dInformation not provided.

^e62% of the patients in the nondysphoric group were female.

^f14 of 20 patients displayed stage III mania.

^gParanoid-destructive group had higher depression scores than euphoric-grandiose group; higher depression scores correlated with favorable lithium response, but not significantly. Rate of lithium response for patients with high depression scores not ascertained.

^h64% of the patients in the nondysphoric group were female.

ⁱAn additional 60 patients displayed cycling between mania or hypomania and depression.

^jAn additional 46 patients had mixed mania with mild depression.

^kAll of the patients in the study were women.

^lSame percentage of females in dysphoric and nondysphoric groups.

more severely ill than nondysphoric patients (5, 6, 22, 23), but the range of severity was wide and overlapped substantially with nondysphoric patients (7, 15–18, 22, 23, 26). Finally, suicidal ideation was frequently observed (3, 4), and the combination of manic and depressive features was noted to constitute a particularly uncomfortable and driven state with a high risk for suicide (49, 50).

In summary, dysphoric mania appears to cover a wide range of symptoms and severity and may include the most severely ill patients with bipolar disorder. The considerable variation in the clinical descriptions of patients, therefore, may be due not only to the lack of standardized operational criteria and differences in patient populations between centers (table 1) but also to the variable nature of the condition.

PREVALENCE OF DYSPHORIC MANIA

Earlier investigators, including Kraepelin in 1921 (1) and Winokur et al. 1969 (3), believed that mixed states are uncommon. Indeed, Silverman (51) wrote that mixed states are so infrequent that a conceptual model of manic-depressive illness need not explain them. However, the more recent studies summarized in table 1 (3–7, 11, 12, 14–26, 28) reported rates of mixed states among acutely manic patients with bipolar disorder ranging from 5% (19–21) to 70% (14). This wide

variation in prevalence across different studies is likely due in part to variations in the criteria used to define dysphoric mania. Indeed, depending on definition—typically of the degree of depression—rates can vary within the same study (22). Nevertheless, despite the wide variation in definition and prevalence across these studies, the overall mean prevalence of 31% (305 of 981 patients) suggests that dysphoric mania is more common than once believed.

DEMOGRAPHIC FEATURES, COURSE OF ILLNESS, AND OUTCOME

Studies comparing demographic and other clinical features of patients with dysphoric versus nondysphoric mania show many inconsistencies. Some studies (3, 6, 13, 14) found that a higher percentage of patients with dysphoric mania than patients with pure mania were female. Most studies reported that patients with mixed and nonmixed mania had similar ages. Himmelhoch and Garfinkel (9), however, noted that adolescents with mania frequently presented with a mixed picture. Also, patients with dysphoric mania have been shown to have a younger (11, 24), similar (26), and older (28) age at onset of illness as well as a longer (11, 26) and similar (24) overall duration of illness compared with patients with pure mania. Regarding episode duration, dysphoric manias have been reported to

be shorter than (36), equal to (3), and longer than (19–21, 26) pure manias.

Studies also varied in the number and type of previous affective episodes experienced by patients with dysphoric mania. Compared with patients with pure mania, patients with dysphoric mania have been found to have more previous episodes (11), similar numbers of previous episodes (22), and fewer previous episodes but more psychiatric hospitalizations (24). Several authors reported that patients with dysphoric mania have higher rates of depression than patients with nonmixed mania early in the course of their illness—with higher rates of premorbid depressive temperament (26), greater likelihood of beginning their illness with a depressive episode (11), and greater numbers of hospitalizations for depressive episodes (24). Onset of dysphoric mania relative to other episodes was also variable. Although some authors (1, 26) reported that mixed manias tend to occur for the first time later in the course of illness, others noted that a substantial proportion of patients with bipolar disorder experience mixed mania as their initial episode (9, 26, 28, 52, 53). Moreover, Dell'Osso et al. (26) found that once a patient experienced a mixed mania, subsequent episodes tended to be mixed.

Regarding outcome, Kraepelin (1) noted that “the course of mixed states occurring as independent attacks appears in general to be lingering; they might be regarded as unfavorable forms of manic-depressive insanity.” Despite some inconsistencies (5, 28), modern studies generally support Kraepelin's observation that patients with dysphoric mania exhibit a poorer prognosis—acutely and over the long-term—than patients with pure mania. Dysphoric patients have been shown to take longer to recover from an acute episode (19–21), to do less well on short-term (23) and long-term follow-up (7), and to be more likely to relapse (22) or to relapse sooner (25) after recovery than nondysphoric patients.

In summary, data on demographic features and course of illness are inconclusive but suggest that dysphoric mania is not limited to any group of patients or stage of illness. However, episodes of dysphoric mania may have poorer short-term and long-term outcomes than pure manic episodes.

FAMILY HISTORY

We found only one study of the families of individuals with dysphoric mania. Using the Family History Research Diagnostic Criteria (54), Dell'Osso et al. (26) compared the first-degree relatives of 49 patients with mixed mania with those of 59 patients with pure bipolar disorder. They found no differences between the two groups in familial affective loading or in family history of suicide or suicide attempts. However, depressive disorders were more common in the families of patients with mixed mania and bipolar disorders were more common in the families of patients with nonmixed mania.

ASSOCIATED CONDITIONS

Few studies have assessed psychiatric or medical conditions associated with dysphoric mania. Winokur et al. (3) noted that of 14 mixed manic-depressive episodes, two occurred postpartum and two were immediately preceded by psychologically stressful events (e.g., the death of a spouse). Dell'Osso's group (26) and Swann et al. (55), however, found that patients with mixed and nonmixed mania did not differ regarding the frequency of antecedent stressful events.

Himmelhoch et al. (7) found that significantly more patients with mixed mania than patients with nonmixed mania had alcohol and substance abuse. They suggested two hypotheses to explain this finding: either dysphoria leads to substance abuse or substance abuse leads to dysphoria. In the first case, the higher rate of substance abuse would presumably reflect an attempt by patients to treat the intense discomfort of dysphoric mania. In the second, the effects of drug abuse—intoxication and withdrawal—might adversely affect the natural course of a manic episode, converting a pure euphoric state into a dysphoric state.

In a follow-up study, Himmelhoch and Garfinkel (9) reported that 45 (71%) of 63 patients with mixed mania, compared with seven (12%) of 58 patients with nonmixed mania ($p < 0.001$), had concomitant neuropsychiatric abnormalities. These neuropsychiatric factors included paroxysmal EEG abnormalities ($N=20$), alcohol and drug abuse ($N=12$), developmental disorders ($N=8$), migraine ($N=6$), seizure disorders ($N=5$), substantial head injuries ($N=4$), and neurological illnesses ($N=2$). Of note, only one of the 45 patients with mixed mania and an associated neuropsychiatric abnormality responded to lithium. In contrast, Strakowski et al. (28) reported that eight patients with mixed bipolar disorder showed no differences from 33 patients with nonmixed bipolar disorder in medical and psychiatric comorbidity.

Very few data are available regarding the relationship of dysphoric mania to other mixed states. For instance, we were unable to locate any studies comparing a group of rigorously diagnosed patients with dysphoric mania with a group of patients with agitated depression or delirious mania. Nevertheless, Himmelhoch's group (32) reported that agitated psychotic depression associated with hypomania or mania was a rare syndrome. In addition, Tandon et al. (34) concluded that patients with mixed depression could be distinguished biochemically from those with mixed mania.

Two studies systematically assessing rapid cycling among patients with dysphoric mania (7, 24) suggested that the two conditions may not be related. Himmelhoch et al. (7) reported that patients with mixed and nonmixed mania showed similar rates of “mood circularity” (defined as episodes of mania and depression *not* separated by periods longer than 2 months). Post et al. (24) reported that patients with dysphoric mania were significantly less likely to exhibit rapid cycling in the year before index admission than were patients with

pure mania. Also, although patients with rapid cycling and patients with nonrapid cycling showed equal peak manic severity at index episode, the patients with rapid cycling showed significantly less dysphoria, anxiety, and psychosis during mania. Patients with rapid cycling, however, have been reported to experience mixed episodes (8, 36). Also, dysphoric mania and rapid cycling may share a greater prevalence among female patients, poorer response to lithium, possible induction by antidepressants, and better response to anticonvulsants (37). Further, the rapid mood shifts described in patients with dysphoric or mixed mania (3, 7-9, 24) may resemble the 24-hour mood shifts described in some patients with bipolar disorder who experienced ultra-rapid cycling (56, 57). However, the relationship between dysphoric mania and ultra-rapid cycling also remains unclear.

Finally, little is known about the relationship between dysphoric mania and personality disorders. Although we were unable to locate any studies using structured interviews to assess this relationship, mixed states (including dysphoric hypomania and ultra-rapid cycling) have sometimes been seen as expressions of borderline personality disorder, largely because these conditions share phenomenological similarities, a higher rate in females, and poor response to lithium (38-40). Akiskal's group, however, argued that many individuals diagnosed with borderline psychopathology may in fact have subtle or "soft" forms of bipolar disorder, including cyclothymia with brief mixed states (38, 39) and prolonged mixed states (e.g., chronic dysphoric hypomania) (40). Although Akiskal's group noted that the abrupt mood shifts in these individuals may give rise to serious characterological disturbances, they reported that psychotherapy is generally ineffective in the absence of adequate pharmacotherapy of the underlying affective instability (38-40).

STUDIES OF BIOLOGICAL TESTS

Studies of the biology of dysphoric mania have primarily examined hypothalamic-pituitary-adrenal (HPA) axis function and plasma or cerebrospinal fluid (CSF) concentrations of neurotransmitters or their metabolites (27). Reports of cortisol function in manic patients in general are inconsistent (14, 27, 58, 59). Some studies (14, 58, 59) found normal cortisol suppression on the dexamethasone suppression test (DST), but others (60-62) found rates of nonsuppression on the DST comparable to those in depression. Nevertheless, several small studies suggested that patients with dysphoric mania may be more likely than patients with pure mania to show DST non-suppression (13, 14, 27). For example, Evans and Nemeroff (14) reported that seven patients with mixed mania (meeting *DSM-III* criteria for both manic and depressive episodes) were DST non-suppressors and that three patients with pure mania were normal suppressors. Five of the patients with mixed mania showed normalization of suppression

when retested after successful treatment. Similarly, of 10 consecutive patients with simultaneous manic and depressive symptoms studied by Krishnan et al. (13), all manifested abnormal cortisol suppression after the DST. Swann et al. (63) recently reported that plasma and CSF cortisol were elevated in patients with mixed mania to an extent similar to or greater than that in agitated depressed patients but were normal in patients with nonmixed mania. In contrast, although one of the studies finding elevated cortisol nonsuppression rates in manic patients (61) did not differentiate between dysphoric and pure mania, one specified that the manic patients studied were not simultaneously depressed (60), while another (62) reported cortisol nonsuppression in five of seven patients with mixed mania and three of nine patients with pure mania.

In studies of neurotransmitter metabolism, Post et al. (24) found that acutely manic patients had significantly higher CSF norepinephrine concentrations than did depressed and euthymic patients and that the degree of norepinephrine elevation correlated with the degree of manic dysphoria, anger, and anxiety. Swann et al. (64) reported similar results with CSF 3-methoxy-4-hydroxyphenylglycol and urinary excretion of norepinephrine and its metabolites, finding no differences between patients with mixed and pure mania.

Regarding other neurotransmitter systems, Tandon et al. (34) found that CSF concentrations of homovanillic acid and 5-hydroxyindoleacetic acid in patients with *DSM-III-R* mixed bipolar disorder were intermediate between those in patients with pure mania and those in patients with major depression; the highest concentrations occurred in the patients with pure mania. Moreover, the mixed group could be subdivided into two groups—mixed manic and mixed depressive. The metabolite levels of these two groups resembled those of the pure manic and pure depressive groups, respectively. The authors concluded that mixed affective states do not exist as a distinct homogeneous entity but are composed of two subgroups representing mixed forms of manic and major depressive states, respectively.

RESPONSE TO BIOLOGICAL TREATMENT

Lithium

We know of no placebo-controlled studies of lithium in the treatment of acute dysphoric mania. However, case reports and case series report the successful treatment of patients with dysphoric mania with lithium alone (4, 5, 12, 14, 52) or in combination with antipsychotics (4, 5, 14) or clonazepam (65). For example, Evans and Nemeroff (14) reported that of seven patients meeting *DSM-III* criteria for mixed bipolar disorder, six responded to lithium alone ($N=2$) or in combination with thiothixene ($N=4$), while the seventh responded only when ECT was administered. Carlson and Goodwin (5) reported that all 14 of the patients they studied with stage III mania (severe mania marked

by prominent dysphoric mood) showed an acute anti-manic response to lithium—sometimes in conjunction with antipsychotics. Many studies, however, suggest that acute dysphoric mania responds less well or less quickly to lithium than does pure mania (6, 7, 9, 15–18, 22, 23). These studies have methodological limitations: all were uncontrolled, some did not clearly specify that lithium was used but only implied that it was, and most used concomitant psychotropics. Nevertheless, if the results of these studies are pooled, 38 (36%) of 105 patients with dysphoric or mixed mania but 86 (75%) of 115 nondysphoric patients responded well to lithium over treatment periods ranging from 24 days to 5 years ($p < 0.001$) (6, 7, 15–18, 22). Moreover, Himmelhoch and Garfinkel (9) reported that of 46 lithium-resistant patients with bipolar disorder, 37 (80%) had mixed mania. These results have led a number of investigators to conclude that dysphoric mania is less responsive to lithium than nondysphoric mania. However, it has been suggested that dysphoric patients may simply need a longer period of treatment before showing an adequate response (15–18).

Long-term studies suggest that prophylactic treatment with lithium is less effective in patients with dysphoric mania than in those with pure mania. Himmelhoch et al. (7) found that patients with mixed mania showed a poorer response to psychopharmacological treatment than patients with nonmixed mania at follow-up ranging from 9 months to 5 years. We know of only one controlled prophylactic drug treatment study of dysphoric mania: Prien et al. (22) found that patients with an index mixed manic episode treated with lithium or lithium plus imipramine for a 2-year period were significantly more likely to experience a recurrence than similarly treated patients with nonmixed manic index episodes. In contrast, in an open retrospective study of 88 patients with manic-depressive psychosis and recurrent depression who had received lithium treatment for at least 1 year, Baastrup and Schou (52) found that 24 (86%) of 28 patients who had experienced mixed episodes during the course of their illness appeared to display a beneficial prophylactic response.

Anticonvulsants

Several studies indicate that patients with dysphoric mania may respond favorably to the anticonvulsant agents carbamazepine and valproate. In a placebo-controlled study of carbamazepine in 19 patients with acute mania, Post et al. (66) found a trend for patients with high levels of dysphoria to respond better than nondysphoric patients. Hayes (67) found that all 12 patients with “mixed bipolar disorders” (the diagnostic criteria were not specified) in an open study of valproate showed improvement in affective symptoms and that six also showed improvement in psychotic symptoms. McFarland et al. (68) found that five of six elderly patients with bipolar disorder in an open-label trial of valproate displayed moderate to marked improvement, including three patients with mixed mania. Calabrese

and Delucchi (36) found that valproate was highly effective in the acute and prophylactic treatment of both manic and mixed episodes (defined by *DSM-III-R* criteria) but less effective in the acute and long-term treatment of depressive episodes in an open, prospective study of valproate in 55 patients with rapid-cycling bipolar disorder. In a follow-up study with 78 patients, Calabrese et al. (69) reported that 54% of patients with mania, 87% of those with mixed states, and 19% of those with depression showed marked acute responses to valproate and that 72% of manic patients, 94% of mixed state patients, and 33% of depressed patients showed marked prophylactic responses. In a controlled comparison of lithium versus valproate in 27 patients with acute mania, Freeman et al. (70) and Clothier et al. (71) found that, unlike the response to lithium, favorable response to valproate was associated with higher pretreatment depression scores (measured by depression factor scores on the Schedule for Affective Disorders and Schizophrenia—Change Version [SADS-C] [72]). Specifically, of 14 patients receiving valproate, all four with mixed mania (defined as *DSM-III-R* mania and a SADS-C depression score greater than 30) responded, compared with five of 10 patients with nonmixed mania.

In contrast, although 21 (46%) of their 46 lithium-resistant patients (80% of whom had mixed mania) responded to “anticonvulsant based therapy,” Himmelhoch and Garfinkel (9) noted that eight of nine patients with “pure presentations” also responded to anticonvulsant treatments. Finally, in a placebo-controlled study of valproate in 36 patients with acute mania (73), our group found that favorable antimanic response to valproate was not associated with levels of depression or dysphoria as measured by individual and composite scores on the Brief Psychiatric Rating Scale (74).

Antipsychotics

We found no controlled studies of antipsychotics in the treatment of dysphoric mania. However, in an open survey of the efficacy of the atypical antipsychotic clozapine in patients with psychotic mood disorders (75), we observed that, of seven patients with bipolar disorder characterized by dysphoric mania, psychosis, and chronic disability refractory to lithium, standard antipsychotics, and anticonvulsants, all showed marked short- and long-term symptomatic and functional improvement in response to clozapine treatment.

Antidepressants

We located only one controlled study of antidepressant agents in the treatment of dysphoric mania. Comparing lithium alone, imipramine alone, and lithium in combination with imipramine in the treatment of 25 patients with mixed mania (16 of whom had mania with mild depression and nine of whom had mania with moderate or severe depression), Prien et al. (22) found that five of eight patients treated with lithium,

all of seven treated with imipramine, and nine of 10 treated with the combination experienced a recurrence. Imipramine treatment, in short, was associated with a greater risk of recurrence. Consistent with these findings, other authors have noted that antidepressants may induce or exacerbate mixed mania or similar mixed states. Akiskal and Mallya (38, 39) reported that 25 patients referred for treatment-resistant depression displayed subacute or chronic mixed states apparently induced by tricyclic antidepressants. These states were characterized by unrelenting dysphoria, severe agitation, refractory anxiety, unendurable sexual excitement, intractable insomnia, suicidal obsessions and impulses, and histrionic demeanor. They improved with antidepressant discontinuation and initiation of lithium or carbamazepine. Koukopoulos et al. (35) found that 45 patients with bipolar disorder suffering from a "mixed depressive syndrome" who met *DSM-III-R* criteria for major depression but not for mania deteriorated when treated with antidepressants—experiencing increased agitation, insomnia, and, in some, suicidal impulses. Patients responded to low-dose neuroleptics, lithium, anticonvulsants, and ECT. Of note, it remains unclear whether mixed manias are more likely to deteriorate than nonmixed manias when exposed to antidepressants.

ECT

Case reports have described the successful treatment of dysphoric mania with ECT (2, 14). In a randomized comparison of ECT versus lithium in 34 patients with acute mania, Small et al. (76) found that patients receiving ECT improved more during the first 8 weeks of treatment than patients receiving lithium. This was especially true of patients with "mixed symptoms of mania and depression and/or extreme manic behavior." Indeed, Small et al. reported that baseline ratings of depression during mania were the strongest predictor of clinical outcome at 8 weeks and that depressive symptoms worsened during lithium treatment but not with ECT—leading the authors to suggest that ECT was more likely than lithium to prevent the "switch over to depression that commonly follows a manic episode."

In summary, a substantial amount of data suggest that lithium may be less effective in the short- and long-term treatment of dysphoric mania than it is in pure mania. Although anticonvulsants and ECT may be more effective in these patients, the studies supporting these treatments are difficult to interpret due to numerous methodological limitations, including variable definitions of dysphoric mania (table 1). Importantly, controlled trials directly comparing lithium, different anticonvulsants, and ECT in adequate numbers of patients with well-defined dysphoric and nondysphoric mania have not yet been conducted. Therefore, whether anticonvulsants and ECT are more effective than lithium in dysphoric mania and whether they are more effective in dysphoric than nondysphoric mania remain

to be definitively proven. It is particularly noteworthy, however, that antidepressants may make these patients worse.

DISCUSSION

Although long recognized, dysphoric or mixed mania remains an understudied and incompletely understood condition. The consensus of the studies reviewed in this paper is that dysphoric mania may be different from nondysphoric mania. Phenomenologic studies suggest that mania accompanied by substantial depression may be more variable, more likely to be associated with depressive delusions and suicidality, and sometimes more severe than pure mania. Studies of demographics, course of illness, and family history suggest that, compared with nondepressed manic patients, dysphorically manic patients may be more likely to be female; to have an earlier age of onset and a longer duration of illness; to have higher rates of depression in their early histories and families; and to have protracted episodes, poorer short- and long-term outcome, and a higher likelihood of recurrence. Biological studies suggest that dysphoric mania may be more frequently associated with non-suppression of plasma cortisol after dexamethasone administration than pure mania. Finally, treatment response studies suggest that, compared with nondysphoric mania, dysphoric mania may be less likely to respond to lithium but more likely to respond to anticonvulsants or ECT.

But what exactly is dysphoric mania? Investigators have variously speculated that dysphoric mania might represent a stage-related or severe form of mania, a transitional state between manic and depressive episodes, a form of typical mania, as well as a distinct affective state. Indeed, different studies suggest that dysphoric mania may be all of these things—in different patients, or in the same patient at different times.

Is dysphoric mania simply severe mania? In their study documenting three stages of mania, Carlson and Goodwin (5) prospectively observed that manic episodes become progressively more severe and more dysphoric over time. In addition, as noted, patients with the most severe (stage III) mania do not differ regarding outcome and lithium response from those with less severe (stage II) mania. The notion that dysphoric mania is a stage-related form of mania—mania at its peak severity—is further supported by findings that depression, anger, and hostility during mania correlate positively with the overall severity of the manic episode (5, 6, 24). However, viewing dysphoric mania simply as severe mania does not account for two observations: many studies (7, 15–18, 22, 23, 26) report that the presence or degree of depression during mania does *not* correlate with ratings of overall manic severity and, perhaps more importantly, patients have been reported to experience dysphoric hypomania, or hypomania associated with prominent depression (6, 11, 39). Thus, although dysphoric mania may include the most severely

ill patients, a wide range of severity in manic symptoms can be present.

Does dysphoric mania represent a transitional state—the so-called switch process between mania and depression or depression and mania? Himmelhoch et al. (7–9) proposed that mixed affective states represent patients getting “trapped” in the switch state from depression to mania. Sitaram et al. (77), in a study of switches into and out of mania in 75 patients with bipolar disorder, found that 35 patients displayed 89 “rapid” switches (occurring in 24 hours or less) and 14 patients displayed 27 “slow” switches (occurring over periods of two to six days)—suggesting that the switch process may sometimes be protracted. This formulation is consistent with the continuum model of bipolar disorder (78), which posits that mania and depression are physiologically similar states that may be quantitatively different and exist along a continuum of severity where depression represents mild to moderate illness, mania represents severe illness, and mixed states represent transitional forms. However, available data indicate that the phenomenology of the switch process is variable. In their longitudinal study of the switch process, Bunney et al. (29–31) found that the most severe degree of depression occurring during mania seemed to occur in patients with “normal” transitions from depression to mania—after the switch had occurred and the patient had become acutely manic. These findings, combined with observations that patients can experience isolated mixed episodes—either as an initial episode or later in the course of illness without preceding or subsequent mood episodes—support the notion that at least some dysphoric manias are not transitional states. Indeed, Berner’s group (42) has identified stable and unstable mixed states, and Cassano et al. (40) have distinguished “pure mixed states” in which the “entire episode is one of mixed symptomatology” and which can be chronic, from the “typically short-lived transitional phenomena between manic and retarded depressive states.”

Is dysphoric mania a distinct state rather than a stage in typical mania? Although many manic patients experience some degree of depressed mood (1–4, 6, 10, 22, 24, 27), the depression is often fleeting or mild (3). The findings of this review suggest that manic patients with prominent or severe depression may be different from those with mild depression. How, then, could dysphoric mania occur as a distinct state? One possibility is that dysphoric mania is a heterogeneous condition with numerous etiologies—reflecting, for example, mixed heredities (the inheritance of two or more illnesses such as bipolar disorder and unipolar depression) or the possibility that mania can be modified by secondary factors (e.g., alcohol or substance abuse, neurological abnormalities, premorbid temperament, personality disorder, or antidepressant treatment) (7–9, 26, 38, 39). Alternatively, adhering to a bipolar model, if the physiological abnormalities causing mania and depression are truly different, or even opposites, dysphoric mania might represent these abnormalities occurring simultaneously, perhaps in different regions of the central nerv-

ous system (e.g., HPA axis overactivity in the hypothalamus and noradrenergic overactivity in the limbic system). This possibility is supported by findings of HPA axis and norepinephrine overactivity in dysphoric mania. Or, taking the “permissive hypothesis” of Prange et al. (79) one step farther, we could posit that perhaps some central abnormality needs to be present in order for the abnormalities underlying mania and depression to occur simultaneously. Yet another possibility is that dysphoric mania is due to a third distinct pathophysiological abnormality.

Recognizing dysphoric mania as a separate affective state may have important clinical and theoretical implications. First, dysphoric mania may be more common than initially thought—possibly even more common than pure mania (4, 6, 22). Indeed, in reviewing studies of the phenomenology of mania conducted during the past 70 years, Goodwin and Jamison (27) concluded that depression and irritability were more common than euphoria in mania. Second, because dysphoric mania is varied in its presentation, it could be confused with a number of other psychiatric conditions, including major depression, agitated depression, atypical depression, delusional depression, ultra-fast cycling, delirious mania, schizophrenia, panic disorder, alcohol and substance abuse, personality disorder, and organic mental disorder (3, 7–9, 12, 15, 27, 32–40). It would be important to distinguish dysphoric mania from these other conditions so that treatments that could potentially worsen dysphoric mania (e.g., antidepressants) would be avoided, while treatments that might be particularly beneficial (e.g., anticonvulsants and ECT) would not go unused and, conversely, so that treatments which might worsen other conditions (e.g., ECT in personality disorder or organic mental disorder) would not be inadvertently misused. Third, certain patients with bipolar disorder might have a greater risk of developing mixed states. These patients might include adolescents or women and those with associated alcohol and substance abuse, high rates of depression in their personal and family histories, neuropsychiatric abnormalities, or a history of treatment with antidepressants. Finally, dysphoric mania might display a more malignant course of illness and have a greater risk for suicide and poorer treatment outcome than typical bipolar disorder.

Theoretically, if dysphoric mania proved to be a separate affective state distinct from depression and mania rather than a stage-related or transitional state, it could be argued that triangular (80) or bidimensional (81) models of mood disorder, which recognize this possibility, may be more appropriate than bipolar or continuum models. Such models would also have to address the relationship among dysphoric mania, ultra-fast cycling, agitated or mixed depression, and other mixed states—disorders that might exist along a continuum of combined manic and depressive symptoms. Agitated depression would represent severe depression with mild mania, and dysphoric mania would represent severe depression with severe mania. Anxious depression, dys-

phoric hypomania, and ultra-fast cycling might represent transitional forms between the extremes of agitated depression and dysphoric mania of greater and lesser severity, respectively. Of note, Emrich (81) has proposed a bidimensional model of manic-depressive illness according to which mixed states are assumed to occur more frequently during the time between peak mania and peak depression but may themselves be of greater and lesser degrees of severity.

To determine whether dysphoric mania is a distinct entity and to test these various hypotheses, operational diagnostic criteria for dysphoric mania need to be developed and tested. Based on this review and on the conceptual definition of dysphoric mania as mania accompanied by prominent depression, we propose that dysphoric mania be defined operationally by the presence of three or more symptoms of major depression during a full manic or hypomanic episode by *DSM-III-R* criteria (appendix 1). We are specifying that three depressive symptoms be present to ensure that the patient displays prominent but not necessarily full syndromal depression. If two depressive symptoms are present, however, a diagnosis of probable dysphoric mania would be made. We propose further that the specific depressive symptoms include depressed mood; markedly diminished interest or pleasure in all, or almost all, activities; substantial weight gain or increase in appetite; hypersomnia; psychomotor retardation; fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt; feelings of helplessness or hopelessness; and recurrent thoughts of death, recurrent suicidal ideation, a suicide attempt or a specific plan for committing suicide. However, we do not include insomnia, reduced appetite, psychomotor agitation, or diminished ability to concentrate because of the difficulty in reliably determining if these symptoms are primarily manic or depressive. Finally, we also propose that patients with rapid cycling should not be classified as having dysphoric mania unless they have experienced three depressive symptoms while also experiencing a full manic or hypomanic syndrome. This would enable patients with rapid cycling to be classified as with and without dysphoric mania.

Systematic studies could compare patients meeting these criteria with patients with pure mania, pure depression, other potential mixed states (e.g., agitated depression, mania with mild depression, and ultra-fast cycling with pure mania), and personality disorder. Until this research is done, investigators and clinicians should be aware that dysphoric mania exists, that it may be more common than realized, that it may be confused with a variety of other psychiatric disorders, and that it may display an outcome and treatment response different from that of nondysphoric mania.

APPENDIX 1. Operational Diagnostic Criteria for Dysphoric Mania or Hypomania

- I. A full manic or hypomanic syndrome by *DSM-III-R* criteria
- II. Simultaneous presence of at least three associated depressive symptoms from the following list (for a definite di-

agnosis of dysphoric mania or hypomania, three depressive symptoms are present; for a probable diagnosis of dysphoric mania or hypomania, two symptoms are present; for a possible diagnosis of dysphoric mania or hypomania, one symptom is present)

1. Depressed mood
2. Markedly diminished interest or pleasure in all, or almost all, activities
3. Substantial weight gain or increase in appetite
4. Hypersomnia
5. Psychomotor retardation
6. Fatigue or loss of energy
7. Feelings of worthlessness or excessive or inappropriate guilt
8. Feelings of helplessness or hopelessness
9. Recurrent thoughts of death, recurrent suicidal ideation, or a specific plan for committing suicide

Problems and Considerations in the Valid Assessment of Personality Disorders

J. Christopher Perry, M.P.H., M.D.

This article reviews evidence for the reliability and diagnostic concordance of structured-interview and self-report questionnaire methods for the diagnosis of personality disorders. The findings of nine studies that compared two or more axis II diagnostic instruments administered to the same groups of subjects are summarized. Across the eight studies with sufficient data, a summary of the overall diagnostic agreement between any two instruments yielded a low reliability (median kappa=0.25) for making individual personality disorder diagnoses. Diagnostic concordance was lower between self-report questionnaire and interview methods than between interview methods. Comparing dimensional scores of different methods did not appreciably improve the level of agreement. The author concludes that current methods for making personality disorder diagnoses have high reliability but yield diagnoses that are not significantly comparable across methods beyond chance, which is not scientifically acceptable. Sources for the disagreement include variance due to different raters, interview occasions, data sources (self-report versus observer report), information bases obtained, and instrument sensitivity to state effects (e.g., mood). Serious problems in assessment validity may also arise from the yes/no format, which, despite probes for confirmatory examples, may fail to distinguish adequately between sporadic occurrences and longstanding patterns. Efforts should be made to improve and demonstrate the validity of axis II diagnostic methods. One route to increasing validity is to improve the clinical interview, because personality patterns are best revealed by the recurring patterns one finds when taking a systematic history.

(Am J Psychiatry 1992; 149:1645-1653)

Prior to the introduction of specific diagnostic criteria, the reliability of personality disorder diagnoses was low. A review of studies from the pre-DSM-III era demonstrated that the mean interrater reliability (kappa) for clinical diagnoses of personality disorders was 0.32 (1). With the introduction of criteria, in the DSM-III field trials the kappa for the presence of any axis II diagnosis was 0.61 in conjoint interviews and 0.54 when independent interviews were conducted (2). However, others (3) reported an overall kappa of 0.41 between independent interviews, with lower concordances for individual disorders (median kappa=0.23). Because low reliability constrains the validity of any assessment, these findings have highlighted the necessity

of adding some procedural guidelines to the nonsystematic clinical interview to improve reliability. The success of the Schedule for Affective Disorders and Schizophrenia/Research Diagnostic Criteria system (4, 5) in yielding reliable diagnoses encouraged the development of both structured-interview and self-report assessments of personality disorders, focusing on the DSM-III and DSM-III-R criteria. As this scientific endeavor has matured, a number of studies have compared different instruments used with the same groups of subjects. This report reviews how well these instruments agree when the same individuals are being diagnosed and discusses issues of assessment validity that are important for both research and clinical practice.

An earlier version of this paper was presented at the annual meeting of the Society for Psychotherapy Research, Wintergreen, Va., June 28, 1990. Received April 24, 1991; revision received March 24, 1992; accepted April 2, 1992. From The Cambridge Hospital and Harvard Medical School, Boston. DESCRIPTION OF DIAGNOSTIC INSTRUMENTS

Following is a brief description of the instruments that have been used in studies comparing the concordance of axis II diagnoses according to DSM-III or DSM-III-R criteria. This list omits instruments for which comparison studies were not found. Reich (6, 7) has reviewed these and other instruments as well.

The National Institute of Mental Health Diagnostic Interview Schedule (DIS) (8), devised for use in the Epidemiologic Catchment Area (ECA) study of *DSM-III* axis I disorders, assesses one axis II disorder, antisocial personality disorder. Each criterion is assessed by one or more questions without probes for examples. Robins et al. (8) reported that the interrater reliability for the antisocial personality diagnosis in a comparison of lay and psychiatrist interviewers was 0.63. Subsequently, the ECA study reported a median lifetime prevalence across its sites of 2.5% overall and 4.5% among the 24- to 44-year-old age group sampled (9).

The Personality Disorders Examination, devised by Loranger (10, 11), is a structured interview yielding 11 *DSM-III-R* personality disorder diagnoses; the 1988 version includes the two (self-defeating and sadistic) listed in the *DSM-III-R* appendix. The questions are organized by topic area rather than by diagnosis, giving the interview a natural flow from the patient's point of view. The current (1988) version includes a number of questions with probes asking for examples or anecdotes following a positive answer. A report on an earlier version (11) yielded high levels of agreement on all diagnoses and high interrater reliability for five diagnoses with sufficient base rates (median kappa=0.80, range=0.70–0.96). Interrater reliability of the dimensional scores for each disorder was very high (median intraclass correlation=0.97). Short-term retest reliability for four diagnoses with calculable kappa coefficients was moderately good (median kappa=0.49, range=0.37–0.56). Standage and Ladha (12) confirmed that overall interrater reliability was acceptable (median kappa=0.63, range=0.38–0.78). Pilkonis et al. (13) obtained an overall interrater reliability kappa of 0.79 for whether any personality disorder was present, and the 6-month retest stability of kappa was 0.52. Kappas for individual disorders were not reported.

The Structured Clinical Interview for *DSM-III-R* Personality Disorders (SCID-II) was devised by Spitzer et al. (14) as a companion to the SCID for axis I disorders. It covers the 11 axis II disorders plus self-defeating personality from the appendix to *DSM-III-R*. The questions are organized by diagnosis, so that all of the criteria for a disorder are assessed together, making it easy for the interviewer to assess one disorder at a time. Interviewers are encouraged to ask additional questions to clarify ambiguous responses, although clarifying questions are not specified. A recent version of the SCID-II uses a series of self-report questions which, if the answers are positive, are then followed by interviewer questions. Reliability findings from this recent version are not yet available.

The Structured Interview for *DSM-III* Personality Disorders was devised by Pfohl et al. (15). The questions are grouped topically rather than by individual diagnosis. Whenever a knowledgeable informant is available, the interviewer is encouraged to ask the informant some of the questions; if discrepancies occur between the subject's and the informant's answers, the criterion is scored on the basis of the more valid answer.

The interrater reliability of the *DSM-III* version was reported for the five disorders with calculable kappas (median kappa=0.75, range=0.45–0.90) (16). A subsequent study confirmed good interrater reliability: six disorders diagnosed two or more times had an interpolated median kappa of 0.83 (range=0.65–1.00) (17).

Two instruments have been devised to capture an analogue measure of the certainty of a clinician's judgment about whether a patient meets the criteria for each personality disorder. Hyler et al. (18) devised the Clinical Assessment Form, which was used in a survey study of clinicians contacted by mail. The Clinical Assessment Form includes a 4-point scale for each axis II disorder (0=no traits, 1=mild traits, 2=moderate traits, and 3=fulfills *DSM-III* criteria). Reliability data are unavailable, and the authors cautioned that it is unclear whether these ratings are comparable to true diagnoses.

A second analogue instrument, the Personality Assessment Form, was devised by Shea et al. (19) to assess axis II personality traits in a group of depressed individuals in the Collaborative Study of the Treatment of Depression. The Personality Assessment Form uses a 6-point scale to rate each of the 11 *DSM-III-R* personality disorder diagnoses and the two provisional diagnoses in the appendix. Each scale is preceded by a definition of the important features of the disorder, and each scale point is anchored by a short statement. A diagnosis is considered present if the patient is given a score of 4 (fits the description "to a considerable extent"). The overall reliability of this categorical cutoff score for the instrument yielded a kappa of 0.48. Subsequently, Pilkonis et al. (13) found that the overall interrater reliability kappa was 0.36 on the basis of intake data, 0.44 when follow-up data were available, and 0.49 when knowledgeable informants were interviewed. The 6-month retest stability of kappa was 0.56 for whether any personality disorder was present.

One self-report instrument, the Personality Diagnostic Questionnaire (20), assesses whether the criteria of the *DSM-III* personality disorders are met. The self-report questions of the Personality Diagnostic Questionnaire are arranged by disorder, making it readily scorable. The revised version includes 152 items for the 11 *DSM-III-R* personality disorder types plus self-defeating personality. A yes/no format is used, and the direction of some items is reversed to mitigate problems of response set. The internal consistency of the 11 original Personality Diagnostic Questionnaire scales was reported (median alpha=0.69, range=0.56–0.84) (Kuder-Richardson formula 20) (18).

A second self-report instrument, the Millon Clinical Multiaxial Inventory (21, 22), purports to measure the same construct dimensions represented in the *DSM-III* personality disorder types, although it does not assess the *DSM-III* criteria directly. It consists of 175 true/false questions representing 20 scales. Reich (7) reported moderately high 8-week retest reliabilities (median correlation=0.75, range=0.60–0.89). A revised version is available, with closer approximation to the *DSM-III-R* personality types.

Concern about the validity of single assessment interviews has persuaded some clinicians and researchers to seek alternative ways to make more valid diagnoses. In the absence of a true validity criterion or "gold standard" for diagnoses, Spitzer (23) suggested what has become known as the LEAD standard, referring to making diagnoses based on "longitudinal expert evaluation using all available data." This typically involves using intake diagnostic assessments, past records, data from informants, and, most importantly, observational data from a subsequent inpatient stay and response to treatment. LEAD diagnoses are then assigned on the basis of a review of all the data by a conference of experts, as has been reported in several studies reviewed below (13, 24-26). In one study the 6-month retest stability of kappa was 0.84 for the presence of any personality disorder, although agreement on individual types was not calculated (13).

THE KAPPA STATISTIC AND DIAGNOSTIC AGREEMENT

Interpretation of the level of diagnostic agreement between any two methods is influenced by the base rate or frequency with which each diagnosis is made by each method in the group studied. For instance, if two instruments each diagnose the presence of borderline personality disorder in 40% of a group of subjects, then by chance alone they should agree on the presence of borderline personality disorder in 16% of the cases (i.e., the product of their base rates, $40\% \times 40\% = 16\%$) and agree on the absence of borderline personality disorder in 36% of the cases (i.e., the product of their base rates for nonborderline personality disorder cases, $60\% \times 60\% = 36\%$), for a total chance level of agreement of 52% (i.e., $16\% + 36\%$). The kappa statistic devised by Cohen (27) corrects for chance agreement by taking the base rates into account to calculate what proportion of the maximum possible chance-corrected rate of agreement was obtained. It does this by taking the observed rate of agreement, subtracting the chance rate of agreement, and then dividing that by the maximum possible rate of chance-corrected agreement (i.e., 1 minus the chance rate of agreement). Studies that determine the level of diagnostic agreement between two interviewers or two instruments use the kappa statistic (chance-corrected concordance) rather than simply reporting the percentage of agreement. However, in modest-sized samples, when a diagnosis occurs at a very low base rate, kappa has high variability (28), and so many studies only calculate kappa for diagnoses occurring 5% or more of the time.

Shrout et al. (28), after Fleiss (29), offered the following guidelines in interpreting kappa values: "Values greater than approximately .75 are generally taken to indicate excellent agreement beyond chance, values below approximately .40 are generally taken to represent poor agreement beyond chance, and values in between are generally taken to represent fair to good agreement

beyond chance." A further characteristic of kappa, or weighted kappa, is that in large samples, the weighted kappa is approximately equivalent to the intraclass correlation, interpretable as a proportion of variance (30, 31). Thus, a kappa value of 0.40 suggests that approximately 40% of the variance in the diagnoses made by two instruments is due to true differences in diagnoses among patients, while 60% is due to other things, such as instrument error.

STUDIES COMPARING DIAGNOSTIC METHODS

The following studies compared two or more diagnostic methods. The emphasis of this review is on the concordance of any two methods for making individual personality disorder diagnoses. Because of the special problems in making clinical diagnoses with the use of self-report instruments only, I have included studies that used at least one observer-rated diagnostic method. The findings for individual diagnoses are displayed in table 1.

Perry et al. (32) compared the DIS with a systematic clinical interview on the *DSM-III* diagnosis of antisocial personality in a group of 70 subjects with personality and affective disorders. Antisocial personality was diagnosed by the DIS in 34 cases and by the clinical interview in 20 cases, yielding a kappa of 0.54. The subjects were subsequently reinterviewed two to seven times over a median of 1 year of follow-up. Data on antisocial behavior were systematically obtained by two different interview methods for each follow-up interval. Subjects diagnosed as having antisocial personality by both intake diagnostic methods showed significantly more antisocial behavior than those for whom the diagnosis was either 1) not present according to both methods or 2) not present according to the clinical interview but present according to the DIS. The discrepant cases (group 2) showed no more antisocial behavior than the group that did not have the diagnosis according to both methods.

Hyler et al. (18) compared Personality Diagnostic Questionnaire diagnoses with clinicians' diagnoses. The data on 552 subjects were obtained by a mail survey of psychiatrists. Each participating psychiatrist administered the Personality Diagnostic Questionnaire to two patients and filled out a clinical assessment form, yielding ratings of clinical certainty that the patients met the *DSM-III* criteria for a given diagnosis, although the exact criteria each patient fulfilled were not noted. The diagnostic concordance between the Personality Diagnostic Questionnaire and clinical diagnosis yielded a median kappa of 0.08 (range = -0.16-0.46). When continuous scores were used for both the Personality Diagnostic Questionnaire and the clinical assessment form, the median Pearson's correlation was 0.31 (range = 0.16-0.51).

Zimmerman and Coryell (17) compared diagnoses made by the Structured Interview for *DSM-III* Personality Disorders and the Personality Diagnostic Ques-

tionnaire in a group of 697 relatives of psychiatric patients and healthy control subjects. Experienced interviewers who had completed graduate work in the social sciences were used. Significantly more subjects were given at least one personality disorder diagnosis by the Structured Interview for DSM-III Personality Disorders than by the Personality Diagnostic Questionnaire (17.2% versus 10.3%); however, the Personality Diagnostic Questionnaire gave more multiple diagnoses. Diagnostic agreement between the two instruments was generally poor (median kappa=0.13, range=0.00–0.38), although agreement about the presence of any personality disorder was higher (kappa=0.32). Comparing dimensional scores from both instruments led to somewhat higher levels of agreement (median Pearson's r =0.37, range=0.24–0.55). The largest correlation (r =0.58) was obtained between the total scores of all personality items endorsed on both instruments.

Hyer et al. (33) compared the revised version of the Personality Diagnostic Questionnaire with two structured interviews, the SCID-II and the Personality Disorders Examination, for 87 applicants for inpatient treatment on a personality disorders specialty unit. Interviews were conducted by experienced clinicians on the same day in a balanced order. The revised version of the Personality Diagnostic Questionnaire had relatively low levels of concordance with either structured interview. The median kappa with the SCID-II was 0.43 (range=0.23–0.63), while the median kappa with the Personality Disorders Examination was 0.37 (range=-0.02–0.54). The Personality Diagnostic Questionnaire was found to be highly sensitive to identifying positive diagnoses made by either structured interview (sensitivity range=75%–100%), whereas its specificities

were low (specificity range=24%–89%). The authors suggested that these findings indicate that the Personality Diagnostic Questionnaire might be a useful screening instrument when personality disorders are highly likely to be present, although it is not a substitute for a structured interview. Agreement between the Personality Disorders Examination and the SCID-II is described below from the authors' report on the enlarged sample (26).

Hogg et al. (34) studied 40 hospitalized patients with schizophrenia of recent onset after the patients had recovered from an acute episode. The Structured Interview for DSM-III Personality Disorders and the Millon Clinical Multiaxial Inventory were administered. The Structured Interview for DSM-III Personality Disorders diagnosed personality disorders in 57% of the patients, most commonly yielding antisocial, borderline, and schizotypal types, while the Millon inventory most commonly found dependent, narcissistic, and avoidant types. The level of agreement between the two instruments on eight diagnoses occurring with sufficient frequency was low (interpolated median kappa=0.14, range=0.00–0.34). When dimensional trait ratings were compared, levels of agreement were somewhat higher (median Pearson's r =0.26, range=-0.03–0.60).

O'Boyle and Self (35) interviewed 20 depressed inpatients with the SCID-II (May 1986 version) and the Personality Disorders Examination (May 1985 version) to rate the DSM-III-R criteria. Reliabilities for the diagnoses obtained were acceptable (Personality Disorders Examination, overall kappa=0.63; SCID-II, overall kappa=0.74). Comparing the two instruments, these authors obtained a kappa of 0.38 for the overall presence/absence of any personality disorder. The reliabili-

ties of the three disorders diagnosed five or more times each yielded a median kappa of 0.23, a low of 0.18, and a high of 0.62. The reliabilities did not change appreciably when four subjects who were psychotic at the time of their initial interviews were excluded. The investigators reinterviewed 17 of the patients after they had recovered from their depression to compare effects of the depressed state on the results of the Personality Disorders Examination. The Personality Disorders Examination dimensional scores were lower for all personality disorder types except paranoid when the subjects were in the nondepressed state, and they were significantly lower for borderline and compulsive disorders. The authors concluded that the modest kappas they obtained were of concern.

Pilkonis et al. (13) carried out an elegant study of 40 patients with major depression in which they compared diagnoses obtained from the revised Personality Disorders Examination and the Personality Assessment Form (scored by the same interviewers) and a LEAD consensus method. The diagnosis of mixed personality disorder was included. Because of the small sample size in relation to the number of disorders, they reported only overall levels of diagnostic agreement, rather than agreement for individual disorders. At intake, personality disorders were diagnosed in 80% of the subjects by the Personality Assessment Form, in 70% by LEAD consensus, and in 63% by the Personality Disorders Examination. The overall concordances between methods were 1) for the Personality Disorders Examination and LEAD, kappa=0.28, and 2) for the Personality Assessment Form and LEAD, kappa=0.21. Raising the threshold of the Personality Assessment Form for a positive diagnosis worsened the level of agreement. Personality Disorders Examination data obtained at intake from a significant other as an informant demonstrated higher reliability with the patient's score on the Personality Disorders Examination repeated at 6-month follow-up (kappa=0.50) and with the LEAD consensus data at 6 months (kappa=0.46).

Pilkonis et al. (13) also examined predictive validity, comparing patients diagnosed with and without personality disorders on the amount of improvement at 6 months on the Global Assessment Scale (GAS), the Beck Depression Inventory, and the SCL-90 total score. They hypothesized that patients with personality disorders should show less improvement. The LEAD consensus diagnoses predicted significant differences in improvement on all three measures, while the Personality Disorders Examination demonstrated improvement on the GAS only, and the Personality Assessment Form demonstrated no significant differences.

Skodol et al. (26) compared the SCID-II and the Personality Disorders Examination data on 100 inpatients. Both interviews were independently administered by professionals in balanced order, generally on the same day. Agreement between the two methods was fair (median kappa=0.50, range=0.14–0.66). Comparing dimensional scores from both interviews yielded better agreement (median Pearson's $r=0.77$, range=0.58–0.87).

After at least 6 weeks of inpatient observation, a LEAD diagnosis was made in 34 cases. The SCID-II demonstrated slightly greater agreement with a subsequent LEAD diagnosis (median kappa=0.25, range=0.03–0.60) than did the Personality Disorders Examination (median kappa=0.25, range=–0.01–0.41). The investigators suggested that diagnoses made according to one structured interview should not be considered comparable to those according to another. This conclusion was strengthened in a subsequent report (36) of different patterns of comorbidity between pairs of personality disorder types across the two interviews. In the same sample, out of 55 possible unique pairs, the Personality Disorders Examination found significant co-occurrence in 29 pairs of personality disorders, compared to 12 pairs diagnosed by the SCID-II.

Jackson et al. (37) gave the Millon Clinical Multiaxial Inventory to 82 inpatients prior to discharge and then administered the Structured Interview for DSM-III Personality Disorders the following day. *DSM-III* criteria were used, and the reliability of the Structured Interview for DSM-III Personality Disorders diagnoses was acceptable (median kappa=0.67). The Millon inventory diagnosed more individuals for six of the 11 individual personality disorders. In the comparison of the two instruments, the base rates of the individual disorders varied by a factor between 1.2 and 6.0. The resulting agreement between the two instruments for categorical diagnoses was a median kappa of 0.18 (range=–0.03–0.53). When dimensional scores for each diagnosis were examined, the agreement rose slightly (median Pearson's $r=0.26$, range=0.02–0.63). The authors concluded that for all but the category of borderline personality disorder, the two instruments demonstrated poor concordance, and for some categories they identified completely different individuals.

SUMMARY OF STUDIES COMPARING AXIS II DIAGNOSTIC METHODS

The level of agreement between instruments across the studies in table 1 can be summarized as good news, bad news, and plain news. The good news is revealed by examining the highest kappa value for agreement on individual diagnoses from each study reporting on more than one disorder. This highest estimate yields a median kappa of 0.54 (range=0.34–0.66) and represents fair to moderate levels of agreement. The bad news is obtained by examining the lowest kappa for agreement on individual disorders from the same studies, which yields a median kappa of 0.00 (range=–0.16–0.23), reflecting very poor chance-corrected levels of agreement. Finally, the plain news is summarized by the median value across studies of the median kappa within each study (i.e., the median of the median kappa values): median kappa=0.25 (range=0.08–0.54). This value has the greatest generalization across personality diagnoses across studies. It reflects that on average, the chance-corrected agreement between diagnostic methods is poor.

These values change somewhat if comparisons with self-report measures are treated separately. For comparisons of interview methods only, the median highest estimated kappa=0.61 (interpolated), the median lowest estimate=0.09 (interpolated), and the median of median estimates=0.25. The studies comparing self-report and interviewer methods reported lower values: the median highest estimate=0.50 (interpolated), the median lowest estimate=-0.01 (interpolated), and the median of median estimates=0.16.

As I have indicated, in large samples the kappa is essentially equivalent to the intraclass correlation, interpretable as a proportion of variance (30, 31). An average chance-corrected concordance of 0.25 between instruments (the median values for all methods as well as for interview methods only) suggests that 75% of the variance in personality disorder diagnoses in the average study represents variance not attributable to the patients. This puts considerable constraint on comparing the findings from any one study with those from another. It is not a scientifically acceptable state of affairs.

The overall situation is improved only slightly when dimensional scores for different methods are compared. Of the four studies that did this, the interpolated median Pearson's r values were as follows: highest=0.59, lowest=0.28, and median=0.34. Pearson's r is used to compare scales with different metrics and is not strictly interpretable in the same way as the intraclass correlation or kappa. Nonetheless, the median figure of 0.34 also reflects an overall poor level of agreement.

The finding of poor diagnostic comparability indicates the necessity of testing and improving the measurement validity of methods for diagnosing axis II disorders, a point made by many of the authors I have cited (13, 17, 26, 32). While some authors have suggested that the use of dimensional scores has advantages over categorical diagnoses (38), the evidence I have described suggests that the use of dimensional scores generally did not raise concordance between methods to acceptable levels.

I suggest two different approaches to this problem. The first is to delineate the sources of measurement problems in current instruments in order to improve them. The second is to develop new methods that assess personality disorders in a conceptually different way, with the potential for better measurement validity.

POTENTIAL SOURCES OF MEASUREMENT ERROR IN CURRENT INSTRUMENTS

Early in the development of a field of study, there is a difficulty in disentangling problems due to measurement validity and those involving construct validity (39). Construct validity is demonstrated when findings converge in a coherent way, such as demonstrating validity in the description, etiology, course, and response to treatment of a given personality disorder and demonstrating that these findings diverge from those for other disorders (40, 41). Construct validity is still at

issue for many of the personality disorders and may therefore constrain any test of the measurement validity of a given instrument. Nonetheless, reviews of the *DSM-III-R* personality disorders (42, 43) suggest that there is sufficient evidence to warrant further study of the present types.

Problems with reliability constrain assessment validity. However, most of the observer-rated instruments for assessing axis II disorders have demonstrated fair to high interrater reliability, thereby minimizing this as a major source of discordance. Dimensional ratings, which have even higher reliabilities, demonstrated only slightly higher correlations (17, 34), except in one study (26). Possible sources of the problem are noted below.

The high reliabilities of the instruments suggest that rater variance due to different levels of experience, training, etc. is not a major source of the lack of agreement among instruments. This may be less true for methods that allow for more clinical judgment. However, studies comparing raters with different levels of training or from different sites are largely lacking.

Self-report questionnaires solicit subjective data, whereas observer-rated interviews include observational data, allowing clinical judgment a role in interpreting the subject's responses. The discrepancy between these data sources has been well described (44) and has properly led to caution in interpreting self-report data on diagnoses (17, 18). This is validated by the findings, shown in table 1, that interview methods demonstrated higher levels of concordance with one another than with self-report instruments. For many criteria (e.g., criterion 7 for narcissistic personality disorder: lack of empathy), a subject might be expected to be a poor judge in the self-report, because the phenomenon requires an external judge.

Occasion variance may introduce some disagreement. Theoretically, personality disorder diagnoses reflect *longstanding* characteristics and should have high short-term stability (45). Some studies minimized occasion variance by having the two different assessments on the same day (26, 33), but they still demonstrated problems in diagnostic concordance.

Some instruments may be sensitive to state effects or changes. This may be suggested whenever test-retest stability coefficients obtained within instruments are substantially lower than their reliabilities. In addition, certain instruments, such as the Personality Diagnostic Questionnaire, may be sensitive to state effects due to depression, while other instruments are not (17).

Instruments do not yield the same databases, thereby introducing some information variance (25). They often assess the same criterion with different questions (17), thereby producing somewhat different data. At present it is not clear how representative of its respective criterion each question is. This problem may be amplified for self-report instruments, because each patient's interpretation of a question may be somewhat idiosyncratic.

The yes/no answer format in most instruments may produce a serious problem. First, it is unlikely that in-

dividuals encode their perceptions and attitudes about themselves and their personalities in the same format as that required by the interview. For example, question 79 from the Diagnostic Interview for Personality Disorders (46) inquires of the subject, "[Have you] often noticed that you don't feel things very deeply?" with a follow-up probe, "Have you ever been told that you seemed like a shallow or superficial kind of person?" This question represents a criterion for histrionic personality. It is readily conceivable that anyone who has low self-esteem or, even worse from a conceptual point of view, a compulsive personality, might respond positively. Asking for examples and then following scoring guidelines should mitigate some scoring errors, but to what extent this is true remains unclear. Even when the interviewer requests an example, the yes/no format simply may not develop sufficient information to ascertain whether a positive answer represents a pervasive, long-standing pattern or a sporadic occurrence. Furthermore, there is a danger that some assessments are overly dependent on the subject's self-report when the criterion reflects an objective phenomenon (e.g., constricted affect, restricted emotionality). The reliance on the yes/no question-and-answer format is a very serious issue, given that all of the instruments use it to a large extent.

The LEAD method of diagnosis may minimize some of these sources of variance. However, its reliability has not yet been established, and the use of data from longitudinal observation during an inpatient hospitalization, while attractive, may not represent the patient's real life patterns (25, 26). Pilkonis et al. (13) did find a good 6-month retest stability of their LEAD diagnosis that at least one personality disorder was present ($\kappa=0.84$), although stability of individual disorders would be expectably lower. Unfortunately, the amount of time and personnel required also detracts from the general applicability of the LEAD method, and standardization of procedures remains to be done.

IMPROVING THE CLINICAL INTERVIEW

Structured interviews were originally devised to cut down on the problem of unreliability in the clinical interview. However, it is possible that assessment validity has been neglected in favor of readily obtaining reliability. An examination of how the clinical interview might improve validity while preserving reliability is warranted.

A good clinical assessment of personality begins with taking a history. The clinician asks the patient to tell important stories from across the life span, preserving the life context in which these occurred. Memorable events and important vignettes tell the story of the patient's relationships with family, loved ones, friends, authorities, and co-workers at home, at school, at work, and at leisure. Symptoms and the onset of illness are seen as occurring in a context, and life stress, so important to the patient, is given its due, helping to differentiate the reaction types defined by Adolph Meyer

from the longstanding maladaptive traits that *DSM-III-R* axis II assesses. The database is an aggregate of dramatic or unusual stories balanced by more commonplace vignettes. This results in a more representative sample of behavior and experience than is obtained in response to a format of yes/no questions, even when these are followed by a request for confirmatory examples. Luborsky and colleagues have found that whenever people tell anecdotes about relationships in interviews or psychotherapy sessions, a limited number of patterns of motives, experiences, and interactions can be reliably identified (47). In the clinical interview, the clinician judges that a criterion is met only after reviewing the whole interview and ascertaining that a long-standing pattern is evident in historical context.

There are some challenges that the clinical interview must meet to demonstrate its scientific respectability. Like the structured interviews, the clinical interview must be replicable and yield highly reliable diagnoses. Both of these aims could be accomplished by the development of guides for conducting the interview and the subsequent rating procedures. This would follow a direction that has proven successful in improving the reliability and comparability of psychodynamic formulations (48), a field which shares much treacherous terrain with axis II. Second, a compendium of good case examples demonstrating both common and unusual patterns that reflect axis II criteria would aid in training clinicians to make comparable ratings. This idea is similar to the idea behind the *DSM-III-R Casebook* (49). Third, there is a need for renewed interest in developing training procedures for conducting the clinical interview, as well as standardizing the ascertainment of clinical interviewing competence.

The results of this review suggest that demonstrating the high reliability of a diagnostic method is not enough to answer questions about assessment validity. We now need studies that address validity by comparing the diagnoses made by any two or more methods against some external criterion of validity, such as etiological factors, prediction of course, and treatment response (41). While several studies have begun this work (13, 32, 36), much more evidence is required before we can say that the axis II diagnoses made by any one method are valid. At present, studies using different methods for diagnosing personality disorders on average can be expected to obtain findings that concur at little better than chance levels and reach different conclusions.

CONCLUSIONS

The introduction of structured interviews and self-report questionnaires to assess axis II disorders has resulted in improved diagnostic reliability within each method. However, comparisons of any two instruments used with the same subjects reveal more diagnostic disagreement than agreement on average. Using continuous or dimensional scoring improves the situation only marginally. This suggests that studies using differ-

ent diagnostic instruments can be compared only with great caution. Whether instruments for which no comparison studies are available (46, 50) will demonstrate better diagnostic concordance remains unknown, but their interview formats are by and large similar to those I have reported. More work on improving the validity of axis II assessments is needed.

There may be a variety of reasons for problems with current approaches. Some, such as variance due to different raters, interview occasion, and state changes, are well-known. Other reasons may be more specific to the problem of assessing personality features, such as establishing that a specific pattern is pervasive and present over time. Using a guided clinical interview offers one potential solution to this problem. Further study is required to determine the assessment validity of current methods for diagnosing personality disorders.

Measuring the Determinants of Work Values for Psychiatrists' Services in the Resource-Based Relative Value Scale Study

Robert A. Dorwart, M.D., M.P.H., Eunice Rodriguez, D.P.H.,
Judith Dernburg, M.A., and Peter Braun, M.D.

Objective: As part of the Harvard resource-based relative value scale study, the authors investigated how well the codes in the Physician's Current Procedural Terminology, 4th edition, or CPT-4, match psychiatric services to the work involved in evaluating and managing patients and how patient care characteristics affect different levels of psychiatric work. **Method:** A random sample of over 200 psychiatrists and subspecialists was asked to use 68 typical clinical examples or vignettes to evaluate services described by CPT codes. Data were analyzed by multivariate statistical methods. **Results:** The survey showed that the existing coding system does not adequately describe the work that psychiatrists do. Within a single code (e.g., 90844, individual medical psychotherapy), there was wide (more than twofold) variation in the estimates, from multiple measurements based on different vignettes, of the amount of work represented. Estimates of work values varied significantly according to treatment setting and patient characteristics: psychiatric services in the hospital showed an average work value 25% greater than that for office services; treating new patients involved 18% more effort than treating established patients; and treating patients described as at risk of harming self or others increased the psychiatrists' work effort by 36%. **Conclusions:** Revisions in coding evaluation and management services in the new Medicare fee schedule for psychiatric services should be further refined and then implemented. These revisions would bring the coding system into line with psychiatric practice, making it a better way of accounting for the relative work involved in treating patients of varying difficulty.

In announcing the final Medicare fee schedule required in 1989 by federal legislation, which mandated physician payment reform (Public Law 101-239), Gail Wilensky, the administrator of the Health Care Financing Administration, called the new Medicare fee schedule "the most significant change in the way Medicare pays doctors . . . since the program began. More importantly, the changes create more equity and consistency in payments to physicians" (Boston, Nov. 22, 1991). The legislation was designed to encourage primary care evaluation and management services, rather than invasive specialty services, by reducing the differences in payments between categories. Under the new Medicare fee schedule, payments will be set nationally, primarily on the basis of the "resource-based relative value scale." The

Medicare fee schedule takes into account physicians' work, overhead, and malpractice costs associated with providing a service; the final Medicare fee schedule is adjusted for geographic variation in practice costs, professional liability insurance, and cost of living (1).

In order to create the Medicare fee schedule, the Health Care Financing Administration worked with a group of researchers at the Harvard School of Public Health under the direction of economist William Hsiao. Over 30 different specialties were studied by the team with the help of numerous specialty consultants. As part of the Harvard resource-based relative value scale study team, and with support from the National Institute of Mental Health, we were responsible for development of the resource-based relative value scale for psychiatry. As described in this article, we obtained relative work values for the full range of psychiatrists' services. In addition, we carried out statistical analyses intended to explain the factors that determine variations in the value of the work done by psychiatrists. We believe these results have implications for potential reform of service codes, which are used in most third-party billing for psychiatrists' services, and for understanding the relation between the coding system and reimbursement for evaluation and management services. Since Medicare intends to reexamine and, where necessary, modify the Medicare fee schedule periodically, our findings may contribute to future coding reforms.

Implementation of the Medicare fee schedule has required changes in the *Physician's Current Procedural Terminology, 4th edition (CPT-4)* codes which physicians use to report evaluation and management services that they have performed. The evaluation and management services are defined to include making diagnoses, counseling and educating patients, developing strategies of care, and following up on treatment. These evaluation and management services are especially relevant for psychiatric practice. In order to assign accurate relative values (defined below) to these services and to ensure equitable payment under the fee schedule, codes must be interpreted and used uniformly by the physicians in a specialty and in all regions of the country. This is not the case with *CPT-4* codes (2).

The Medicare fee schedule requires that *CPT-4* codes represent similar resource costs to all who use them. We wished to answer the question, How much variation is permissible before resource costs are to be considered dissimilar? Deciding how wide a range of work values may fall within the scope of a single code that is used for billing is an important issue which must be addressed in crafting a coding system. Wide ranges may result from ambiguity in the definition of the code, differences in physician practice styles, or heterogeneity of types of service provided. When the range is large, physicians who regularly provide services at the low end of the range of work values will be relatively overcompensated for that code, while those whose services are regularly at the high end will be undercompensated. Too wide a range of work values in the framework of a fee schedule provides an incentive to provide services at the low end of the range.

In previous research, the Hsiao group found that the range of variation within a code for most medical evaluation and management services lies within 30% of the mean (3). On the basis of these findings for evaluation and management services studied in other specialties, we propose that visit codes in which physician work varies by more than a twofold difference not be used for payment purposes and that the service be coded into better-defined categories to specify the content of the work for each code.

In this article we analyze two aspects of variation in the work values of psychiatrists that are important for designing a better payment system for psychiatry. First, we identify services for which there is at least a twofold variation within a code. Second, we examine characteristics of patient care that may influence the level of work. Importantly, these characteristics are not currently incorporated into the *CPT-4* coding system for specialty-specific psychiatric services.

We formed a panel of psychiatrists, selected by a process previously described (4), to constitute a Technical Consulting Group for psychiatry. Physicians' work for each service is measured to take into account the time required to provide the service (in minutes) and three factors that determine the intensity of work for the time spent: 1) the mental effort, knowledge, and judgment required, 2) the technical skill and physical effort expended, and 3) the level of stress, due to risk to the patient or others, including the physician. In our investigation, intensity was measured operationally as the work per unit time required to perform a particular service (5).

We elicited suggestions from the Technical Consulting Group for factors that were thought to influence the intensity of psychiatrists' work. It was suggested that for a particular service (e.g., psychotherapy), the range of intensity would vary, depending on characteristics of the patient, the nature of the treatments provided, the setting of care, and other factors specific to the services provided. For psychiatry, the factors that were hypothesized to be associated with different levels of intensity included site of treatment (office and hospital), age group of the patient, whether the patient is new or established, management of psychotropic medications, number of people seen in a session, and the degree of risk of harm by the patient to himself/herself or others (dangerousness).

METHOD

The general method for construction of the resource-based relative value scale and for the estimation of work values is described in detail elsewhere (6). In collaboration with APA, we used definitions of services based on *CPT-4* to develop a list of the 68 most frequently performed services. In order to measure the range of work values of commonly used *CPT-4* codes, we composed for each of these codes clinical vignettes of varying complexity and severity of symptoms that

require varying durations of treatment. We included most of the available CPT-4 billing codes used for psychiatric services and added several services for which there were no specific CPT-4 codes, such as play therapy for a young child. We then obtained for each vignette, through a national survey, ratings of the intraservice and total work involved. The "total work" includes time actually spent with the patient during an encounter in the office (intraservice) plus time spent in preparation before the visit and on follow-up activities related to the encounter (6).

To illustrate, several vignettes representing varying treatment complexity were constructed for psychiatric services. One vignette was selected by the psychiatrists of the Technical Consulting Group as typical of a psychotherapy visit, and others were devised to be more or less difficult. The standard vignette chosen for comparison was the following: "50 minutes of psychotherapy in the office, fourth session, for a married 25-year-old male, originally referred by an internist, suffering from the recent onset of panic attacks. The panic attacks have not interfered with his employment, and he is responding positively to medication and psychotherapy." For purposes of comparison, this service was given a value of 100. An example of a vignette of a service of relatively greater difficulty is "one session of psychotherapy in the office, for a 45-year-old male with a five-year history of a bipolar mood disorder, who is on lithium carbonate and is seen every other week for issues related to conflict in his marriage and at work, and who reveals a plan to kill himself during the session. After assessment you take steps to begin involuntary admission to the hospital." The study sought to quantify, on the basis of estimates by practicing psychiatrists, the magnitude of the difference in work values between these two services, based on the definition of work mentioned above. Clearly, the second service requires more time, mental effort, and judgment and entails greater risks during and after the visit. It not only requires more time but requires a higher intensity of work. Respondents assigned a numerical rating of 235 to this vignette, indicating that it is more than twice as difficult as the standard.

A random sample of psychiatrists was drawn from the American Medical Association (AMA) 1988 Physicians' Masterfile. The sample was stratified geographically by 10 census regions and by specialty-specific distributions within each region. Board-certified psychiatrists represented approximately 80% of the sample. We excluded psychiatrists who worked fewer than 20 hours a week in patient care or who were in residency training. After mailing questionnaires to our sample, we obtained their responses shortly thereafter in telephone interviews conducted by a professional survey organization. Respondents rated services with the method of magnitude estimation, comparing the work of all psychiatric services to the reference standard service vignette described earlier (7).

We further divided the sample into three parts, with an oversample of psychoanalysts and child psychiatrists

in the second and third subsamples, respectively. Survey questions were correspondingly matched to the respondents, so that certain basic core services were presented to all respondents, but services for children were presented primarily to the child psychiatrists. We questioned whether there were systematic subspecialty differences in work values within psychiatry and tested for this possibility with an analysis of variance (ANOVA). Each psychiatrist was classified according to primary subspecialty: child psychiatry, psychoanalysis, or general psychiatry. The Technical Consulting Group consultants felt that further division of the sample into additional subspecialties was unlikely to be necessary. An ANOVA was performed on each group (i.e., child psychiatrists, psychoanalysts, and general psychiatrists) and on the entire sample for a common set of core services, with physician and service as independent variables. When we compared the sums of squares for the interaction terms, we found little variation (less than 2%), suggesting little difference in estimates of total work across the three groups.

We used multiple regression techniques to analyze the determinants of work value for the total work of the service (preservice, intraservice, and postservice work) as well as for intraservice work alone; however, only results from using total service as the dependent variable are reported here. A set of independent variables measuring possible predictor variables of work value was then created. We analyzed the residuals of our model for randomness, normality, constancy of error variance, and appropriateness of the regression function. We also examined the independent variables to ensure that there was no significant multicollinearity.

RESULTS

Of an initial sample of 300 psychiatrists drawn from the AMA 1988 Physicians' Masterfile, 209 completed the survey—a 71% response rate. We found that 25% (N=52) of our sample were child psychiatrists, 17% (N=36) were psychoanalysts, and the remaining 58% (N=121) were general psychiatrists or other subspecialists.

Eighty-three percent of the sample was male, and the average age was 51.5 years. Eighty-two percent of the respondents were board certified, and the average net income was \$118,000 per year. We asked psychiatrists to describe their most recent week's work, separating their practice activities into several categories of work (e.g., total hours worked, hours in the office). The typical psychiatrist reported spending 51 hours per week at work, excluding time spent on-call (an additional 9 hours per week). The characteristics of the respondents were similar to the ones described in *The Nation's Psychiatrists* (8), but the group differed slightly from the general population of psychiatrists in being slightly older, spending a few more hours per week seeing patients, and having a higher proportion of board-certified physicians.

FIGURE 1. Range of Variation of Total-Service Work Values Within Selected CPT-4 Codes for Psychiatry

Figure 1 presents the range of observed total work values for selected CPT-4 codes for psychiatry. All five codes exhibited some variation in the mean work values associated with a vignette or description; CPT-4 codes 90843, 90844, and 90801 for psychotherapy and diagnostic/evaluation services varied twofold or more from the lowest to the highest value. When compared to the smaller average variations in work values described in other medical services, such large variations in the work values within the CPT-4 code suggest that the code may be too general and covers more than one distinct service. We decided to look at these psychiatric services and to analyze their determinants of work values by calculating total-service work values for the selected psychiatric services described in figure 1. For the most common services, such as individual psychotherapy or group and family therapy, the total work value for the code was a weighted average for several vignettes. Group psychotherapy was calculated per patient. These relative values were derived for use in the Medicare fee schedule; however, in our subsequent analysis reported below, we sought to explain underlying reasons for the variation in total work value across different examples of a service within a single code.

Figure 2 shows how our hypothesized characteristics affect total work values for the services described by the CPT-4 codes shown in figure 1. The base service is set arbitrarily at 100 work units (e.g., a typical office visit for an established patient, an adult under age 65, who is taking no psychotropic medications and is not at high risk of harm).

If the session is for a new patient, defined as the first three visits, the total work value is 18% greater than for an established patient. If there is evidence for potential harm to the patient or someone else, total work value increases 36% on average. When the service is provided in the hospital, the work value increases by 25%. When effects are combined, the work value of a visit can vary more than twofold. For example, the work of an initial

FIGURE 2. Percentage Change in Total-Service Work Values for Selected Psychiatric Services in All Settings^a

^aThe base service is an individual encounter in the office with an established patient who is not taking medication and is not at risk of causing harm to self or others. Percentage differences in total work values are compared to base service.

^bSignificant difference at the 0.05 level.

^cSignificant difference at the 0.01 level.

session of psychotherapy in a hospital with a patient who is potentially dangerous to himself has a work value more than twice that of the base service, although both services take the same amount of time.

In addition to the variables shown here, we included time as a determinant of work value for psychiatric services. Our results show that for an increase of 1% in the time of a visit, total work increases by 0.8%. Thus, when all other characteristics of the regression are held constant, the results show that work value increases relative to time, but at less than a 1:1 ratio. If the value of a 50-minute visit is 100, then a 25-minute visit will have a relative work value of 60. As was found to be the case in other medical specialties, time appears to be the single most important determinant of work value for psychiatric services.

DISCUSSION

The resource-based relative value scale approach to payment will make an important change in payment for all physicians, but especially for those providing evaluation and management services. Psychiatry stands out as one specialty in which time spent with patients plays a very important role. The most commonly provided office-based service is psychotherapy, in which time spent with patients is a crucial aspect of treatment (9). Our results indicate the importance of time in assessing psychiatrists' work, but in addition we have shown that, holding time constant, services billed using the same CPT code category may vary widely in intensity or difficulty.

We found that three variables reached statistical sig-

nificance as factors influencing the intensity of work: new patients, hospital care, and risk of harm. New psychiatric patients require more effort than established ones, as is the case in medicine generally. The evaluation of such patients requires careful and thorough interviewing, formulation of a differential diagnosis, and often the gathering of collateral information and data. It is also reasonable to assume that on average, patients treated in the hospital are more acutely ill and require greater diagnostic efforts and more complex treatment interventions than those seen in the office. This fact is recognized by the idea of payment of the physician for "floor time" in the hospital, involving coordination of care, review of records, and interaction with staff members on a treatment team. Patients who are likely to be at risk of harming themselves or others are more difficult to treat than nonthreatening patients. Risk of harm on the part of the patient increases the importance to society of the physician's judgment and often increases the potential medical malpractice liability for the physician and the hospital.

The finding concerning dangerousness of the patient deserves further clarification. Dangerousness in this study included a variety of aspects of potential risk of harm to self or others, including ideas or plans for self-destructive behavior. This is necessarily a limited definition of dangerousness, somewhat akin to the standards used by many state governments to evaluate individuals for civil commitment. Obviously, many patients have self-destructive symptoms but are not candidates for hospitalization; making this clinical judgment is a frequent burden of treatment for psychiatrists.

The finding of the importance of dangerousness in the weighting of estimates of work values raises perplexing policy issues in designing a physician payment system, such as how to verify the clinician's judgment about the degree of dangerousness if the diagnosis would result in higher charges for the treatment. Another problem is how to design a billing and reporting system that would not violate patient confidentiality. This problem of confidentiality arises in psychiatry because of the stigma associated with a diagnosis of schizophrenia, for example, and in other specialties in designing payment for treating medical patients with AIDS or addictions, for example. We are faced with the dilemma of how to take into account the need to compensate physicians for the important clinical work that they do, while at the same time protecting patients' rights to privacy and recognizing limitations of providers' judgment.

In addition to the variables we found to be statistically significant, there were others for which we found some variation that did not reach statistical significance. These variables describe factors that we hypothesize may have an influence on the intensity of work but which require further investigation. For example, psychiatrists rated services involving the treatment of young children as requiring more work than services for adults. Perhaps this is related to problems in communication requiring the interpretation of non-

verbal behavior and fantasy play, or perhaps it is related to the need to spend additional time in family interactions. Other variables, such as the influence of medications, are difficult to interpret and deserve further study. Certain specific categories of services also required considerably more work, not just more time, than did regular psychiatric office visits. Forensic consultation was one of these; however, there is currently no CPT-4 code for this service.

What are some of the implications of our analysis for coding psychiatric services? The wide range of variation in work values for the psychotherapy code (90844), which specifies 45- to 50-minute sessions, raises the question of whether it should be divided into two or three different levels of care. The finding that services provided in the hospital require more work on average than do comparable services in the office suggests the need to examine whether there should be a different code assigned according to the setting in which the services are provided. Proposals for coding according to setting for psychiatric services provided to partially hospitalized patients and those in residential care settings are now being developed; new codes for other psychiatric interventions in other settings, such as the emergency room, may also be desirable. The finding of greatly increased work associated with potential dangerousness deserves further investigation and discussion of coding options.

CONCLUSIONS

This study demonstrates that the classification and coding system on which the resource-based relative value scale is based—CPT-4—inadequately captures the breadth and depth of practice in psychiatry. We found a range of variation within CPT-4 codes for commonly provided services, such as the psychotherapies, that extends beyond the bounds that might be considered reasonable or desirable for a uniformly applied reimbursement system. Our findings suggest the need for further refinement of codes for psychiatry. Our findings may be useful because Medicare intends to make needed adjustments and revisions annually for the Medicare fee schedule.

In this study, we demonstrated that there are identifiable clinical and situational aspects of psychiatrists' work that show a statistically significant amount of variation in both the intraservice work and the total work of psychiatric services: new patients, work in the hospital, and potential dangerousness of patients. These findings raise important questions about the current structural basis used by Medicare for the implementation of a fee schedule for psychiatric evaluation and management services. Two of the determinants of work value identified in our analysis could be incorporated into the new Medicare fee schedule and would lead to a system in which coding and payment would be more closely related to physicians' work. The status of the patient (new versus established) and the site of

care (office versus hospital) can be reliably verified and operationalized. Dangerousness as a patient coding characteristic is, as we noted, more problematic. As implementation and refinement of the Medicare fee schedule for psychiatry proceed, we believe that further efforts to address the issues identified in this study may lead to a fairer payment system.

Assessment of Lineality in Bipolar I Linkage Studies

Sylvia G. Simpson, M.D., Susan E. Folstein, M.D.,
Deborah A. Meyers, Ph.D., and J. Raymond DePaulo, M.D.

Objective: To assess lineality in families of bipolar I probands, the authors used direct interviews of family members to reclassify families initially categorized as unilineal by family history. **Method:** The families of 1,800 treated bipolar I probands were screened by the family history method with multiple informant. If the proband had one or more affected sibs and one apparently unaffected parent, the parents (and then other available first- and second-degree relatives) were directly interviewed by psychiatrists. **Results:** Of the 1,800 families screened, 56 were apparently suitable unilineal families with multiple affected members; 46 families were interviewed directly. After interviews with the parents, 12 families (26.1%) were found to be bilineal. Direct interviews of all available relatives in the 34 remaining families revealed that only 22 (47.8% of the 46 interviewed families) were unilineal or probably unilineal and 12 were probably bilineal. The probably bilineal families had a significantly higher proportion of siblings with unipolar disorder. In addition, the affected sibs from the probably bilineal families tended to have earlier onsets but had significantly fewer symptoms in the most severe depressive episode. **Conclusions:** Fewer than 50% of bipolar I families appearing unilineal according to family history were found to be unilineal by direct interviews. The phenotypic differences between the affected sib from the probably bilineal families and those from the unilineal and probably unilineal families suggest differences in genetic mechanisms. These findings highlight the need to systematically assess lineality in all families considered for bipolar I linkage studies.

(Am J Psychiatry 1992; 149:1660-1662)

The importance of genetic heterogeneity as a potential problem in resolving the genetics of bipolar I affective disorder has been widely discussed (1-5). The related issue of bilineality (the existence in both parental lines of the same illness that affects the proband) has received less attention (5, 7). The phenomenon of mating by two individuals with major affective disorders is common and may represent assortative mating (8-11), although other explanations are plausible. Since bilineal families may introduce into the family's gene pool more than one gene that contributes to the bipolar I phenotype, they present a substantial problem for ge-

netic linkage analyses, which can detect efficiently only one disease gene per family. Therefore, carefully selected unilineal families are required to test the hypothesis that some forms of bipolar illness have mendelian (monogenic) inheritance. The mendelian hypothesis will not have been tested rigorously until a sufficient number of unilineal bipolar I families have been completely genotyped, by using genetic markers spanning the entire genome, and analyzed.

Since the limits of the phenotypes associated with the bipolar genotype(s) are not clear, there is some uncertainty about which families are unilineal and which are bilineal. Most studies (12-14) suggest that the phenotypes considered to be affected should include bipolar disorders, schizoaffective disorder—manic, and recurrent unipolar disorders, but it is possible that other clinical conditions, when seen in a family ascertained through a bipolar proband, also may be manifestations of the bipolar genotype (15). The Research Diagnostic Criteria (RDC) (16) diagnoses of single episodes of major depressive disorder, hypomanic disorder, intermittent depressive disorder, agoraphobia, panic disorder, and obsessive-compulsive disorder and DSM-III-R diagnoses of pathological gambling, anorexia nervosa,

and bulimia nervosa have all been associated with affective disorder in one or more family studies (15, 17, 18). If these uncertain phenotypes are ignored in the supposedly unaffected parent of a bipolar proband but are, in fact, genetically related, then bilineality would not be detected. If, on the other hand, these phenotypes are genetically unrelated to bipolar disorder, then such families would be unilineal.

There are widely differing views as to what constitutes bilineality and how to handle it in linkage analyses. Merikangas et al. (6) believe that a family in which both parental lines have any of the conditions which have been associated with affective disorder may be bilineal and should not be accepted for genetic linkage studies of bipolar disorder. Bilineality may have contributed to the loss of evidence favoring linkage to chromosome 11p loci in the reevaluation of the Old Order Amish study. The pedigree, as described in published reports, contains three affected but apparently unrelated individuals among the progenitors (19). In a negative study using X-chromosome markers, Berrettini et al. (14) excluded branches of families clearly affected by bilineality but left unexamined one-third of the fathers assumed to be unaffected but who had affected offspring. If any of these fathers were affected, they may have passed on to their offspring an autosomal form of the disease.

Since currently it is not possible to know which families are truly unilineal, we have examined directly both parental lines of probands for evidence of affected or uncertain phenotypes. We report here clinical data from 34 families that, after direct interviews of both parents, siblings of the proband, and all other first-degree relatives, were classified as unilineal, probably unilineal, or probably bilineal.

METHOD

Initially we selected families that each contained a treated bipolar I proband with two or more siblings who were affected with bipolar I disorder, schizoaffective disorder—manic, bipolar II disorder with recurrent major depressions, or recurrent unipolar disorder. Currently we are ascertaining families through treated bipolar I probands with one or more affected sibs. We require that the assumed unaffected parent be alive and available for examination.

To find suitable families, we screen the psychiatric inpatient units, day treatment center, and outpatient clinics at a university hospital and an urban medical center in Baltimore. Our collaborators in Iowa screen the psychiatric inpatient and outpatient units at a university hospital.

When we find a prospective study family, we obtain informed consent, take a thorough family history of both parental lines from multiple informants (20, 21), and tentatively assign the family to one of four categories: 1) unilineal, 2) probably unilineal, 3) probably bilineal, and 4) bilineal. These are defined as follows:

1. *Unilineal*—the required unaffected parental line (parent, sibs of the parent, and grandparents) has no phenotypes classified as uncertain or affected.

2. *Probably unilineal*—the required unaffected parental line has no affected phenotypes but has some uncertain phenotypes.

3. *Probably bilineal*—the required unaffected parent has a parent or sibling with an affected phenotype.

4. *Bilineal*—both parents are affected.

Families that appear unilineal or probably unilineal are studied further by means of direct interviews. All available relatives are interviewed by one of two psychiatrists (S.G.S. or J.R.D.) with the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (22), to which we have added supplemental questions on medical conditions, pathological gambling, eating disorders, and treatment response. A blood sample is obtained to establish a lymphoblastoid line. If, by SADS-L interview, a key member of the “unaffected” parental line is diagnosed as having an affected phenotype, the family is designated as bilineal or probably bilineal and is not used for linkage analysis.

Diagnoses are made by using the RDC (16). A best-estimate diagnosis is made on the basis of the SADS-L data and information from psychiatric records, the individual's treating psychiatrist(s), and first-degree relatives. To avoid false positive diagnoses in siblings, we use a narrow definition of the affected phenotype. To detect bilineality (introduced by grandparents and parental sibs, as well as parents) we also use a narrow definition of the unaffected phenotype. An individual with an associated condition who cannot be confidently categorized as either unaffected or affected is designated as having an uncertain phenotype. The category of uncertain phenotype includes individuals with 1) threshold cases of affective disorder, such as hypomania, intermittent depression in the absence of recurrent major depressive episodes, or a single episode of major depression; 2) nonaffective conditions, such as panic disorder, obsessive-compulsive disorder, and anorexia nervosa; and 3) probable phenocopies, i.e., affective disorders secondary to physical illnesses (e.g., stroke and hypothyroidism), trauma, or medications.

The statistical analyses used were chi-square analysis of discontinuous variables, analysis of variance with post hoc analysis for continuous variables, and analysis of the age-adjusted residuals to take into account the differences in age at interview across groups.

RESULTS

To date, we have screened more than 1,800 bipolar I pedigrees and have systematically recorded the reasons for rejection for the last 1,488 pedigrees screened. The reasons for rejecting families on the basis of family history were, in descending order of frequency, insufficient number of living relatives (29.2%), obvious bilineality (20.6%), refusal to participate (16.2%), insufficient number of affected relatives (12.3%), unsuitable pro-

band (12.1%), and unavailability of key relatives (6.3%). The most striking finding was that many families that initially appeared suitable later had to be excluded for bilineality. Of the families meeting the family structure requirement of at least two affected sibs (including the proband), 50% had to be excluded because of bilineality after more family history was obtained and/or direct interviews were done.

On the basis of family history, 56 families were accepted, and the parents in 46 of these families were interviewed. Twelve families were dropped after this stage because of bilineality. Most of the sibs and other available family members in the 34 remaining families were interviewed. Ten of the 68 parents were not interviewed (eight were deceased, and two refused), and 26 of the 122 siblings were not interviewed, mostly for geographical reasons; none of the un interviewed family members were included in the data set. After direct interviews with all available family members, we reclassified 12 of these 34 families as unilineal, 10 as probably unilineal, and 12 as probably bilineal. Table 1 shows the age and sex of the probands, parents, and siblings in these 34 families. There were no significant group differences in the sex ratio for either the probands or the siblings when affected and unaffected sibs were considered together. There were significantly more male unaffected sibs than female unaffected sibs in the probably bilineal group ($\chi^2=4.37$, $df=1$, $p<0.05$). While the average ages at interview were similar in the three proband groups, there were significant differences in age among the parents and siblings: the parents and sibs were oldest in the unilineal families and youngest in the probably bilineal ones (table 1).

Probands

The bipolar I probands from the 12 unilineal, 10 probably unilineal, and 12 probably bilineal families were compared in terms of characteristics of depression and mania. There were no significant differences in the number of symptoms, number of episodes, age at onset, longest duration of an episode, or number of hospitalizations for either mania or depression between the bipolar I probands from the unilineal families and those from the probably unilineal and probably bilineal families.

Siblings

Because all the families were required to have at least two affected siblings, the prevalence of affective disorder was high in all three groups (table 2). The sibs in the probably bilineal families had a significantly higher rate of unipolar disorder than did the sibs in the unilineal families, 29% versus 6% (table 2). There was a higher proportion of bipolar I sibs in the unilineal families than in the probably bilineal families, but this difference did not reach significance.

As shown in table 3, the affected sibs in the unilineal families had significantly more symptoms in the most severe depressive episode than did those from the probably bilineal families. The affected sibs from the three types of families were also compared with respect to age at first outpatient treatment and number of hospitalizations. Because age at interview was significantly different across the three groups, this variable was taken into account by using age-adjusted residuals. The sibs from

the unilineal families tended to be oldest at first outpatient treatment, and those from the probably bilineal families were the youngest (table 3). The number of hospitalizations was not significantly different across the three groups.

DISCUSSION

The purpose of this paper is to describe our experience with a two-stage method for assessing lineality in bipolar I families ascertained for a genetic linkage study. We found that fewer than one-half of the families who appeared to be unilineal according to family history were unilineal according to direct interviews. There were phenotypic differences between the affected sibs from the unilineal and the probably bilineal families. The probably bilineal families had a significantly higher proportion of sibs with unipolar disorder. In addition, the sibs from the probably bilineal families tended to have an earlier onset but had significantly fewer symptoms in the most severe depressive episode.

High Prevalence of Bilineal Families

Our initial plan, based on the requirements of our linkage analysis design, was to ascertain unilineal families with three or more affected sibs. Clearly unilineal families with this structure have proven difficult to find. Even after we changed our family structure requirement to include families with only two or more affected sibs (including the proband), almost one-half of the families appeared to be bilineal. This experience is consistent with the results of the study of affected siblings of probands with bipolar mood disorder by Pritz and Mitterauer (23), who found that as the number of affected sibs per family increased, so did the probability that the family was bilineal. Their information on affected family members was based largely on hospital records, sometimes going back six generations. Sixty-eight percent of their families with three affected sibs were bilineal, compared to 46% of their families with two affected sibs.

Some of the bilineality may be accounted for by assortative mating, the tendency for mated pairs to be more similar for some phenotypic trait than would be expected if they were chosen at random. Merikangas and Spiker (11) studied the spouses of 56 affectively ill inpatients and found that 54% had lifetime histories of some psychiatric illness and 43% had lifetime histories of affective disorder. Eighty-five percent of their bipolar inpatients had spouses with histories of some psychiatric disorder, compared to 45% of the unipolar inpatients. However, this does not clarify the genetic importance of bilineality in general or assortative mating in particular in the transmission of bipolar disorder. Assortative mating could complicate linkage studies in a mendelian dominant (but genetically heterogeneous) disease by producing affected offspring who have different genotypes. On the other hand, assortative mating

TABLE 3. Clinical Features of 62 Affected Siblings of 34 Bipolar I Probands in Families Classified as Unilineal by Family History and Reclassified by Direct Interviews

Lineality According to Direct Interviews	Siblings' Characteristics					
	Age at First Outpatient Treatment (years) ^a		Number of Admissions		Number of Depressive Symptoms in Most Severe Episode ^b

^aNearly significant difference between siblings in unilineal families and those in probably bilineal families ($F=2.34$, $df=2, 58$, $p=0.06$).

^bSignificant difference between siblings in unilineal families and those in probably bilineal families ($F=3.85$, $df=2, 53$, $p=0.02$).

could contribute to the high prevalence of a polygenic disorder and produce mendelianlike segregation ratios in nuclear families.

Possible Explanations for Clinical Differences Between Unilineal and Probably Bilineal Families

Comparison of clinical data from the unilineal and probably bilineal families suggests that the unilineal families may have a mendelian form of bipolar disorder. First, 90.0% of the affected siblings had bipolar I or II disorder (table 2). This contrasts with the probably bilineal families, in which a significantly higher proportion of the siblings had unipolar disorder. Second, the affected sibs from the unilineal families had significantly more symptoms in their most severe episodes of depression than did those from the probably bilineal families. On the other hand, those from the probably bilineal families had a younger age at onset.

In the probably bilineal families, the offspring may be getting different genes (possibly major and minor) for affective disorder from both parents, and thus one would expect to see more of a spectrum of affective disorders in those families. It may be that if both parents are carrying minor genes for affective disorder, their offspring are more likely to develop unipolar than bipolar disorder.

The greater number of symptoms in the most severe depressive episode in sibs from the unilineal families than in sibs from the probably bilineal families may indicate that where bipolar disorder breeds true, it is more severe.

We have no explanation for the finding that the siblings from the probably bilineal families were significantly younger than those from the unilineal families at the time of the study; it may be a spurious finding. We are presenting our findings so that others may test them. In summary, our current reasoning about our preliminary findings is that families which manifest se-

vere bipolar disorder may be more likely to have a monogenic form of the disorder, whereas families with a mixture of both bipolar and unipolar phenotypes which have clinically milder illness may be more likely to have a multigenic form of bipolar I disorder.

We have attempted to reduce the number of sporadic cases of depression by requiring that our subjects with unipolar disorder have recurrent major depressions. We have also looked at indexes of diagnostic stability for our unipolar subjects (24). Our unipolar subjects had an average of 3.4 (SD=1.2) episodes of depression and 6.5 (SD=1.2) of a possible eight RDC depressive symptoms in their most severe episodes. Fifty percent were treated with medications for their depressions. While we cannot be sure that recurrent depression of this severity always represent genetic forms of depression, we hope that this requirement will eliminate many sporadic cases (25, 26).

We have tried to detect phenocopies by searching for possible organic causes of major affective disorder in affected family members. If the proband appeared to have a possible organic affective disorder, he or she was designated as an unsuitable proband and the family was not accepted into the study. If the disorder of an affected family member appeared to have an organic etiology, that individual was designated as having an uncertain phenotype and will not be included in the linkage analysis. If this individual were a sib or parent of the unaffected parent, this would not result in the family's being classified as probably bilineal. A true phenocopy in the sib or parent of the unaffected parent, however, would result in false labeling of the family as probably bilineal. It is hoped that the prevalence of these phenocopies is low.

Thus, we have made a serious effort to designate sporadic or nongenetic depression as an uncertain or unknown phenotype. The issue of whether even recurrent cases of depression should be considered genetic cases of depression will be reviewed before linkage analysis.

Strategies for Ascertaining Unilineal Families

Because of the current limitations of genetic linkage methods and nonreplication of recent linkage findings for bipolar I disorder, a cautious approach to family selection is warranted. Only a set of clearly unilineal families will allow a test of the hypothesis that bipolar I disorder can be inherited through mendelian dominant transmission. On the basis of our experience, we recommend several strategies for ascertaining unilineal bipolar I families.

Two-step method for detecting bilineality. The first step consists of taking an extensive family history of both parents' families. A family that appears to be unilineal moves on to step 2 (direct examination); the parents are interviewed first, followed by the sibs of the proband, then the aunts, uncles, and grandparents. This requires that the unaffected parent and some of his or her sibs and/or parents be available for direct interview. If a parent, aunt, uncle, or grandparent on the "unaf-

ected" side of the family is found by interview to be affected, we recommend that the family be designated as probably bilineal and excluded from the sample for linkage analysis. The probably bilineal families can be used in clinical comparisons with the unilineal families. In addition, after some of the genes for bipolar disorder have been found, these families will be of great interest for genetic studies.

Other authors have given general prescriptions for detecting bilineality to exclude such families from linkage analyses (6, 7). However, to our knowledge, no fully operationalized methods (including who must be directly interviewed and which phenotypes must be excluded) have been published to date. We have not compared our method with other methods. A pragmatic test of our method will be undertaken in the planned linkage analysis; however, comparative assessments of methods for detecting bilineality would also be useful.

Narrow definitions of phenotypes. We recommend very narrow definitions of affected and unaffected status. A high threshold for calling a parent of a proband unaffected is warranted in order to identify and exclude potentially bilineal families. It is also recommended that any psychopathology in the parents, aunts and uncles, and grandparents of the proband be described and documented in order to quantitatively assess the risk that they are genetically affected.

Using a high threshold for designating sibs as affected will decrease the number of phenocopies (false positives), which may have a major effect on the linkage analysis.

Relatives who are not clearly affected but who have conditions that have been associated with the bipolar phenotype should be designated as having uncertain phenotypes (3, 7) and followed longitudinally.

Selection of families with bipolar disorder in at least two generations. While it may be that only a minority of bipolar I cases may result from dominant transmission of a single gene, it is most conservative to look first at families which appear to be of this type. Selection of families with bipolar I disorder in at least two generations should increase the probability of finding unilineal families and of finding mendelian forms of bipolar I disorder.

Family structure requirement. Unilineal families with one affected parent and only one affected sib in addition to the proband are highly informative. This family structure provides almost as much linkage information as those with three affected sibs (27) and may be less likely to be bilineal.

Systematic ascertainment of families. We studied a number of self-referred families with three or more affected sibs, and almost all these families were bilineal. Therefore, we recommend that families be ascertained by systematic screening of clinical services.

CONCLUSIONS

The mode of inheritance of bipolar I disorder is unknown. While there may be mendelian dominant forms

of the disorder, they may be uncommon. If the current searches for mendelian forms of the disorder are to have the best chance of success, an adequate resource of unilineal families must be studied with DNA markers spanning the entire genome.

Finding suitable unilineal families for genetic linkage studies is a labor-intensive process requiring extensive screening of patient populations in treatment facilities. However, the ascertainment and careful clinical study of a sufficiently large number of such families should increase the probability of positive linkage findings and decrease the probability of nonreplication of positive findings.

Schizoaffective Disorder and Affective Disorders With Mood-Incongruent Psychotic Features: Keep Separate or Combine? Evidence From a Family Study

Wolfgang Maier, M.D., Dirk Lichtermann, M.D., Jürgen Minges, M.D., Reinhard Heun, M.D., Joachim Hallmayer, M.D., and Otto Benkert, M.D.

Objective: This study investigated whether the distinction between schizoaffective disorder and affective disorders with mood-incongruent psychotic features as described in DSM-III-R is reflected by aggregation of schizophrenia in the families of probands with the former disorder and aggregation of affective disorders mainly among the relatives of probands with the latter type of disorders. **Method:** The probands were 118 inpatients with definite lifetime diagnoses of DSM-III-R schizoaffective disorder or a major mood disorder with incongruent psychotic features according to structured clinical interviews. Diagnostic information on 475 of the probands' first-degree relatives was gathered through direct interviews (with 80% of the living first-degree relatives) or the family history approach. The rates of affective and psychotic disorders among these relatives were then compared with those among the relatives of a comparison group of 109 interviewed individuals from the general population who were matched on sociodemographic factors to the inpatient probands. **Results:** With regard to the familial aggregation of schizophrenia, the DSM-III-R distinction emerged as valid. However, the risk of unipolar affective disorders was enhanced in the families of all of the subgroups of patients studied. The unipolar/bipolar distinction in both DSM-III-R diagnostic groups was reflected by distinct patterns of bipolar disorders in the relatives. **Conclusions:** The results partly support the DSM-III-R dichotomy of schizoaffective disorder and affective disorders with mood-incongruent psychotic features. Although the differences between these two diagnostic groups were significant, the magnitude of the differences remained relatively modest.

(Am J Psychiatry 1992; 149:1666-1672)

There is broad agreement that the lifetime diagnosis of patients with a lifetime comorbidity of pure affective episodes (manic episode/major depressive episode) and pure schizophrenic episodes should adhere to the hierarchical principle that schizophrenia takes priority. On the other hand, the classification of the co-occurrence, within the same episode, of a major affective syndrome and a psychotic syndrome that is not due to the affective syndrome is highly controversial. Different criteria (e.g., which of the two syndromes preceded the other one; the relative duration of temporal overlap; preponderance of symptoms versus severity of symptoms) are considered to be crucial by the various diagnostic

schedules. A variety of diagnostic classifications with various degrees of inclusiveness have been proposed. The Research Diagnostic Criteria (RDC) (1) suggest three main diagnostic categories (affective, schizoaffective, and schizophrenic disorders), with one diagnostic category, schizoaffective disorder, for episodes with two syndromes showing considerable temporal overlap. The RDC further recommend subdividing this diagnosis according to the relative preponderance of a particular syndrome during the episode, resulting in a schizophrenic and an affective subtype of schizoaffective disorder. The subclassification according to affective and schizophrenic syndromes was constructed in order to dissolve the heterogeneous group of schizoaffective disorders (2, 3) into two homogeneous subgroups. The support for this suggestion from family study data, however, has been ambiguous. On the one hand, Baron et al. (4) were able to discriminate probands with schizoaffective disorder who had an elevated risk of schizophrenic disorders but no increased

risk of affective disorders from those with the reversed pattern by subdividing the probands as recommended by the RDC. On the other hand, some family studies of schizoaffective disorder that used this manner of subtyping revealed more similarities than differences between these two subgroups with regard to the diagnostic patterns of familial aggregation (5).

DSM-III-R was a new attempt to split the group of patients identified by the RDC as having schizoaffective disorder by redefining the distinction proposed in the RDC (the RDC affective subtype corresponding to *DSM-III-R* mood disorders with mood-incongruent psychotic features and the RDC schizophrenic subtype corresponding to *DSM-III-R* "true" schizoaffective disorder) (6). These definitions were more precisely worked out than the definitions of the RDC subtypes and focus on a required minimum duration of psychotic symptoms in the absence of affective syndromes. In contrast to the RDC's three main categories (affective, schizoaffective, and schizophrenic disorders) *DSM-III-R* was oriented toward Kraepelin's dichotomy by splitting the range of overlapping affective and psychotic conditions into two subgroups belonging to the two main categories: those which are allocated to affective disorders (termed mood disorders with mood-incongruent psychotic features) and those allocated to psychotic disorders (schizoaffective disorder). The crucial differential criterion is whether the mood-incongruent psychotic features mainly occur when the criteria for a major affective syndrome are fulfilled (affective disorder with psychotic features) or whether psychotic features are also present for 2 weeks or longer after the affective syndrome has remitted or before the affective syndrome will become apparent (schizoaffective disorder).

The validity of the RDC definition of schizoaffective disorder is supported by family studies that were able to demonstrate familial aggregation of schizoaffective disorder. Two family studies of probands with affective as well as psychotic syndromes according to *DSM-III-R* criteria have been published up to now (7, 8); the study by Maj et al. (8) presented data on unipolar depression only, not on bipolar patients. Both studies are very clearly in support of *DSM-III-R*. Limitations inherent in these two *DSM-III-R*-based studies suggest that their conclusions be considered as preliminary. The study by Kendler et al. (7) was an evaluation of the material collected by the Iowa 500 study; the authors conceded the limitation of this approach in their article. The study by Maj et al. (8) is unusual among the universe of family studies using the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) in that it reported extremely low rates of affective disorders in families of control subjects and of probands with affective disorders. In particular, the lifetime risks among families of control subjects were substantially lower than those in all epidemiological surveys and in comparison groups of family studies using the same instrument (SADS-L). (There was, for example, an epidemiological survey that used the same interview in the same country and reported a 1-year prevalence rate of 8.5%

for mood disorders [9]). Furthermore, schizophreniform disorder (*DSM-III-R*) and other psychotic disorders (including schizoaffective disorder) were not recorded for family members. Therefore, replications of the results found and the conclusions drawn by Kendler et al. and Maj et al. are needed.

This report refers to a family study that recruited inpatients and their families irrespective of their diagnoses. Patients with *DSM-III-R* diagnoses of affective disorders with mood-incongruent psychotic features or schizoaffective disorder and their families were selected and compared, grouped according to their *DSM-III-R* diagnoses, with subjects recruited in the general population and their families. Probands who had affective disorders with mood-congruent psychotic features and their families were not included in the study. Taking into account the bipolar/unipolar distinction, we tested the hypothesis inherent in *DSM-III-R* that families of probands with affective disorders with psychotic features are at greater risk for affective disorders but not for schizophrenia, whereas schizoaffective probands might carry an elevated familial risk of schizophrenia. Bipolar subjects who reported full-blown manic episodes were included; those who had hypomanic episodes only were excluded from the study.

METHOD

Psychopathological and Final Diagnostic Assessment

The probands and their relatives were directly interviewed with an extended version of the Schedule for Affective Disorders and Schizophrenia—Lifetime Version Modified for the Study of Anxiety Disorders (SADS-LA) (10). The SADS was originally based on the RDC but also includes the criteria in the mood disorders section of *DSM-III-R*. In order to classify psychotic disorders also according to *DSM-III-R*, the corresponding sections on schizophrenia and psychotic disorders of the Structured Clinical Interview for *DSM-III-R* (SCID) (11) were applied. Schizotypal personality disorders were assessed by means of the personality disorders module of the Structured Clinical Interview for *DSM-III-R* (SCID-II) (12).

We used the family history approach (13) to ask the relatives of probands about psychiatric syndromes in the other members of the family being assessed (with exception of the proband). The family history method provides a semistructured interview for RDC and *DSM-III-R* diagnoses of major affective, schizoaffective, and schizophrenic disorders and of anxiety disorders, alcoholism, drug abuse, and eating disorders. Minor disorders and personality disorders are not included.

The personal interviews and the family history assessments were conducted by 11 research assistants (advanced medical students with clinical experience in psychiatry or young physicians) after a common training program of at least 20 sessions with all instruments to

be used. Test-retest reliabilities for all *DSM-III-R* diagnoses discussed in this article were tested separately and were acceptable (κ values higher than 0.75). The reliability study has been published separately (14).

The final diagnostic assessment according to the RDC and the *DSM-III-R* criteria was performed by two experienced psychiatrists (W.M. and R.H.), who combined the information obtained by personal interview (if available), the family history information obtained from all sources available, and the case notes (if present) and made a final diagnosis using the RDC and *DSM-III-R* manuals. The same procedure was applied to both probands and relatives. The best-estimate diagnoses (15) were allocated independently to probands and relatives. The diagnostic assessments we report were lifetime diagnoses made by following a hierarchical procedure: schizophrenia has priority over schizoaffective disorder, which is followed by bipolar and then by unipolar major affective disorders.

Recruitment of Probands

Patient probands. The families under study were derived from an extensive family study including probands with all kinds of affective disorders, schizophrenia, and other psychotic disorders. Inpatients consecutively admitted to the psychiatric hospital of the University of Mainz between January 1988 and August 1989 and aged between 20 and 70 years were first screened by the treating physician for somatic factors causing psychiatric distress. Patients without an established organic etiology, without a history of seizures, and without dementia were further screened by means of the SADS-LA. Patients reporting a previous or current episode of any psychotic or major affective disorder according to the RDC or *DSM-III-R* criteria were included in the family study if at least one living first-degree relative agreed to be personally interviewed with respect to his or her and the family's psychiatric history and status. Additionally, patients with a history of the above-mentioned disorders as evidenced by case reports and by clinical judgment were included even if they could not be interviewed during their stay in the hospital because of the severity of their psychological impairment. For all members of this subgroup it was required that at least one living first-degree relative be accessible for the personal interview.

Five hundred twenty-five patients were selected as probands for the family study. Only probands with unambiguous evidence of mood-incongruent psychotic features and hence a *DSM-III-R* diagnosis of either schizoaffective disorder or a major affective disorder with mood-incongruent, not mood-congruent, psychotic features were selected for this report. Only if both clinicians deciding on the best-estimate diagnoses agreed on the definite presence of either of these two disorders, and if they were able to rule out unambiguously the diagnosis of schizophrenic disorders or affective disorders without mood-incongruent psychotic features, was the proband included in the sample. Of the

original group of 525 patients, 140 fulfilled these requirements and presented with a definite lifetime diagnosis of either schizoaffective disorder or a major affective disorder with mood-incongruent psychotic features according to the *DSM-III-R* criteria.

To draw valid conclusions from comparisons of diagnostic subtypes by familial loading, diagnostic certainty in subtyping the probands and consistency in applying the diagnostic criteria across subtypes are crucial requirements. By adhering to these principles, we excluded 22 additional patients with either of the disorders being studied (and their families) from the group of 140 patients and their families for the following reasons. 1) Twelve patients reported episodes with overlapping psychotic and affective syndromes, but the available information (including medical records) was not sufficient or unequivocal enough to decide with certainty between schizoaffective disorder and mood disorder. It was not possible to determine whether delusions and/or hallucinations were present for 2 weeks or longer without prominent affective symptoms. 2) Ten patients fitted the *DSM-III-R* requirements for schizoaffective disorder or a mood disorder with incongruent psychotic features but also reported hypomanic episodes accompanied by incongruent psychotic features without ever having suffered from a full-blown manic episode (bipolar II probands). Families of these probands were not included, as the *DSM-III-R* classification is inconsistent at this point: bipolar II probands who have major depressive episodes with mood-incongruent psychotic features may be considered to have bipolar disorder not otherwise specified. However, *DSM-III-R* does not recognize bipolar II schizoaffective disorder and classifies bipolar II probands with episodes of schizoaffective disorder, depressive type, as having unipolar schizoaffective disorder, depressive type, ignoring the bipolar condition. Exclusion of bipolar II probands and their families enabled a consistent application of the unipolar/bipolar dichotomy to psychotic mood disorders and schizoaffective disorder.

Diagnostic information from 475 first-degree relatives (aged 18 years or older) of the remaining 118 probands with schizoaffective disorder or mood disorders with incongruent psychotic features was gathered by either the family history method or the family study method.

Comparison probands. One hundred nine comparison probands with at least one living and accessible first-degree relative were recruited from the general population of the same area from which the inpatient probands came. The sampling scheme was based on the socioecographic characteristics of a randomly drawn subsample of the index patients (probands), to which the comparison group probands were matched pairwise by sex, age, educational level, occupational status, and residential district. The recruitment of the comparison subjects was assisted by a professional marketing institute. As recommended by Tsuang et al. (16) and Kendler (17), these probands were not screened for diagnoses. Information was obtained from 432 relatives

(aged 18 years or older) of the comparison probands by the family study or the family history method.

Investigation of Family Members

Diagnostic information on probands' first-degree relatives who refused to be interviewed or who were dead was obtained by the family history method from at least one informant per family. The interviewers were blind to the diagnostic status of the probands. We also collected medical records if we had the consent to do so.

Table 1 displays the characteristics of the probands and the relatives studied.

Statistical Methods

The presentation of familial rates combines data on relatives who were personally interviewed with data on those for whom only family history information was available for the following three reasons. 1) The ratios of personally interviewed relatives were very similar across groups (table 1). 2) The rate of affected relatives (combining all disorders) obtained by the family history method was lower than the rate yielded by the family study method, but not significantly so ($\chi^2=2.2$, $df=1$, $p>0.05$) in any of the five groups of relatives compared. 3) The majority of relatives who were not interviewed personally were classified by systematically collected information from multiple informants, not just a single one.

Since *DSM-III-R* schizoaffective disorder and affective disorders with mood-incongruent psychotic features do not differ in the distribution of their ages at

onset (in the life table analysis comparing age at onset of all probands or relatives with schizoaffective disorder to age at onset of those with psychotic mood disorders, $\chi^2=0.4$, $df=1$, $p>0.10$), and since the distribution of the current ages of the probands and relatives did not differ among the schizoaffective, the psychotic affective, and the comparison groups (table 1), age correction was not necessary for comparing the proband groups under study. Therefore, we simply report the relative frequencies of disorders (in percents) in the families of the various proband groups. The familial rates for the proband groups were compared by means of chi-square tests (two-tailed); there was 1 degree of freedom unless otherwise indicated.

Because schizophrenia and related disorders are rare in community samples, it is likely that some cells in contingency tables will be empty or show only a very low relative frequency. Thus, a correction procedure for the chi-square test is required; we selected the pseudo-Bayesian approach (18) for this purpose.

RESULTS

Table 2 displays the relative frequencies of psychotic and affective disorders in families by proband type. All disorders under consideration were more frequent in the families of all patient groups than in the families of the healthy comparison probands. When combining the unipolar/bipolar subgroups of probands and relatives, we found that the following disorders were significantly more common among relatives of probands with schizoaffective disorder than among relatives of the comparison subjects: schizophrenia ($\chi^2=6.4$,

$p=0.01$), schizophreniform disorder ($\chi^2=4.6$, $p=0.02$), schizoaffective disorder ($\chi^2=6.4$, $p=0.01$), psychotic mood disorders ($\chi^2=4.4$, $p=0.02$), nonpsychotic unipolar mood disorder ($\chi^2=8.9$, $p<0.01$), and nonpsychotic bipolar mood disorder ($\chi^2=3.2$, $p=0.05$). The following disorders were more common among relatives of probands with major mood disorders with incongruent psychotic features: schizophrenia ($\chi^2=2.5$, $p=0.05$), schizophreniform disorder ($\chi^2=2.2$, $p=0.07$), schizoaffective disorder ($\chi^2=3.1$, $p=0.05$), psychotic mood disorders ($\chi^2=4.8$, $p=0.02$), nonpsychotic unipolar mood disorder ($\chi^2=11.2$, $p=0.001$), and nonpsychotic bipolar mood disorder ($\chi^2=4.2$, $p=0.03$). The familial rates of minor affective disorders (if a hierarchical rule is applied to the diagnoses) were not different between either group of patients and the comparison subjects (schizoaffective disorder, $\chi^2=0.0$, $p>0.10$; affective disorders with mood-incongruent psychotic features, $\chi^2=0.2$, $p>0.10$).

In the comparison of the schizoaffective disorder and the psychotic mood disorder proband groups for familial rates of nonaffective psychotic disorders, divergent trends appeared (table 2). The risk of schizophrenia as well as schizoaffective disorder was nearly twofold

higher for the family members of the schizoaffective proband group than for the relatives of the affective disorder proband group, but not significantly so ($\chi^2=0.4$, $p>0.10$, and $\chi^2=0.3$, $p>0.10$, respectively).

Five cases of DSM-III-R schizotypal personality disorder (1.6%) without psychotic disorder (i.e., without schizophrenia or schizophreniform, schizoaffective, or other psychotic disorders) were found among the directly interviewed relatives of the patients with schizoaffective disorder or psychotic mood disorders, whereas two cases (0.7%) were found among the interviewed relatives of the comparison subjects (data not shown). Schizotypal personality disorder was primarily observed in the families of probands with unipolar disorder: two cases (3.4%) among the relatives of probands with unipolar schizoaffective disorder, two cases (1.8%) among the relatives of probands with psychotic unipolar major depression, and one case (1.8%) among the relatives of bipolar schizoaffective probands.

Table 2 gives information about the nature of schizophrenia and schizophreniform disorder in the families of probands with schizoaffective or psychotic mood disorders. Only half of the schizophrenic relatives also reported a previous depressive, manic, or schizoaffective

tive episode. No consistent pattern emerged when the proband groups were compared by the percentages of schizophrenic/schizophreniform relatives who showed comorbid major affective syndromes on a lifetime basis.

The families of patients with schizoaffective disorder, as well as those of patients with mood disorders with incongruent psychotic features (ignoring the unipolar/bipolar dichotomy) were at significantly greater risk for any subtype of mood disorder than the families of the comparison subjects ($\chi^2=14.6$, $p=0.001$, and $\chi^2=20.4$, $p=0.001$, respectively). However, the families of the two types of patient probands did not significantly differ in their rates of affective disorders ($\chi^2=0.0$, $p>0.10$).

An additional feature of the data displayed in table 2 is most remarkable: bipolar affective disorders and bipolar schizoaffective disorder (i.e., conditions with at least a full manic syndrome at one time for at least 8 days) predominantly aggregated in the families of probands with bipolar affective disorders or bipolar schizoaffective disorder. The elevation of the risk for bipolar disorder was significant in the families of both proband types ($\chi^2=14.3$, $p=0.001$, and $\chi^2=14.7$, $p=0.001$, respectively). Neither the families of the unipolar schizoaffective proband group nor the families of the unipolar affective disorder proband group (with mood-incongruent psychotic features) were at greater risk for bipolar affective or bipolar schizoaffective disorders ($\chi^2=1.4$, $p>0.05$, and $\chi^2=0.9$, $p>0.05$, respectively).

The risk for unipolar depression and unipolar schizoaffective disorder was enhanced in the families of patients with any subtype of disorder compared to the families of the comparison subjects. The elevation of the risk of unipolar major depression was significant for the families of probands with psychotic unipolar depression ($\chi^2=8.5$, $p=0.01$) and those with unipolar schizoaffective disorder ($\chi^2=9.0$, $p=0.01$) as well as for the families of probands with psychotic bipolar disorder ($\chi^2=4.8$, $p=0.02$) and those with bipolar schizoaffective disorder ($\chi^2=9.8$, $p=0.01$). The link of bipolar schizoaffective disorder and of psychotic bipolar affective disorder to schizophrenia was as strong as the link of unipolar schizoaffective disorder and of unipolar affective disorder to schizophrenia. The familial rates for schizophrenia or schizophreniform disorder were not different for the relatives of the unipolar and the bipolar proband groups ($\chi^2=0.1$, $p>0.10$).

DISCUSSION

The global rate of occurrence of disorders characterized by an overlap of affective and schizophrenic syndromes in the families in this study is comparable to that in other reports. Previous studies, summarized by Gershon et al. (19), found morbid risks, depending on particular subtypes, between 0.0 (20) and 7.4 (21) for broadly defined schizoaffective disorder. If we combine the risk among relatives for *DSM-III-R*-defined schizoaffective disorder and affective disorders with mood-in-

congruent psychotic features, the familial rates in our study vary between 3% (five of 165 relatives of probands with unipolar depression with mood-incongruent psychotic features) and 6% (five of 85 relatives of probands with schizoaffective disorder, bipolar type), which is within the range spanned by previous studies.

The distinction between schizoaffective disorder and affective disorders with mood-incongruent psychotic features as proposed by *DSM-III-R* received some support in our family study: 1) schizophrenia and related conditions were more closely related to *DSM-III-R* schizoaffective disorder than to psychotic affective disorders, and 2) *DSM-III-R* schizoaffective disorder was more common in families of probands with this condition than in families of probands with affective disorders. The first finding is in agreement with the two other reports on this *DSM-III-R* distinction, those of Kendler et al. (7) and Maj et al. (8), and with the earlier report by Baron et al. (4). The second finding is also in agreement with Kendler et al. (7) and—if the differences between the RDC and *DSM-III-R* criteria are ignored—with Baron (4), whereas schizoaffective relatives are not mentioned by Maj et al. (8). Both of these findings are at variance with those of Angst et al. (5), who found the same familial background for the schizophrenic and the affective subtypes of a broadly defined group of patients with affective as well as psychotic syndromes. However, because the familial loading varied across the groups of probands in our study, it does not support the combination of the four subgroups of patients under a unitary diagnostic category (schizoaffective disorder) as is recommended by the RDC.

However, substantial disagreement with Baron et al. (4) and—for the unipolar subtypes—with Maj et al. (8) is also apparent from our family study. As previously reported by Angst et al. (5), we found schizoaffective disorder and psychotic affective disorders to be related to both schizophrenia and nonpsychotic affective disorders. As far as nonpsychotic unipolar major depression is concerned, this finding also contradicts the reevaluation of the Iowa 500 study by Kendler et al. (7), but it does not do so for nonpsychotic bipolar disorder. The risk for nonpsychotic bipolar disorder was elevated in the families of schizoaffective probands (defined by *DSM-III-R* criteria) in the report by Kendler et al. Consequently, the Iowa 500 data also indicate some link between a schizophrenia-type variant of schizoaffective disorder and affective disorders (nonpsychotic), even though Kendler et al. did not stress this relationship in their discussion.

Beyond the similarity of our results to those obtained by Angst et al. (5), the features moderating the variation of familial risks across the various subtypes of probands differ between the two studies. Two aspects are most noticeable in this respect.

1. We found that the familial loading for affective disorders varies along the unipolar/bipolar dichotomy; the schizoaffective/psychotic affective distinction had no impact on the variation of familial rates of affective disorders. Angst et al. (5) reported that neither the bipolar/

unipolar nor the schizo-dominant/affect-dominant distinction was relevant in this respect. Evidence from the literature mainly favors our conclusion: all studies (except that of Angst et al.) report a strong relationship between bipolar schizoaffective disorder and bipolar affective disorder (19, 22). The majority of studies also report virtually equal familial rates of nonpsychotic unipolar depression for unipolar and bipolar schizoaffective proband groups.

2. Our data reveal that the familial risk for schizophrenia is higher in the more schizophrenic than in the more affective proband group; the bipolar/unipolar distinction was not associated with different familial risks for schizophrenia. Angst et al. (5) found no impact of the schizo-dominant/affect-dominant distinction in this respect, but they reported the unipolar depressive subtype to be more closely related to schizophrenia than the bipolar subtype. At this point our results receive support from the literature. All family studies (except the one by Angst et al.) that have subdivided a broadly defined group of schizoaffective conditions (including mood disorders with incongruent psychotic features) into a schizophrenic/affective type dichotomy found the more schizophrenic subtype to be more closely linked to schizophrenia than the more affective subtype. The evidence for a particularly close relationship between the bipolar subtype and schizophrenia is less strong (22).

A peculiar finding of our study was the familial homotypy observed for the combination of bipolar affective and bipolar schizoaffective disorder. The exclusion of probands with hypomania but without a lifetime history of mania might have contributed to this homogeneous pattern. Previously, Baron et al. (4) reported a similarly distinct pattern for the combined bipolar group. On the other hand, Kendler et al. (7) and Gershon et al. (19) found a greater rate of nonpsychotic bipolar disorder in families of probands with unipolar schizoaffective disorder or psychotic affective disorders who never presented with manic syndromes. We cannot offer a convincing explanation for these divergent results; we can only exclude the impact of the differences between different classification schedules, since Baron et al. (4) and Gershon et al. (19) used the RDC, whereas Kendler et al. (7) used *DSM-III-R*. Furthermore, the follow-up period for the probands examined by Kendler et al. lasted for decades, and therefore in that particular study, the unipolar cases were truly unipolar and not hidden bipolar cases.

It has not been established whether schizoaffective disorder represents a particular diagnostic entity or a variant of either schizophrenia or affective disorders (22). Our study found a higher rate of a particular diagnostic subgroup in the families of probands who belonged to the same subgroup. However, there were much higher familial rates of affective or schizophrenic/schizophreniform disorders in both subgroups under study. This statement remains true if the four diagnostic subgroups we studied are collapsed into one group. Most investigators have been motivated by similar observations to deny that schizoaffective disorder is

a distinct form of psychosis (23). However, the validity of this conclusion depends on the relative base rates of the three conditions (schizophrenia, affective disorders, and the combination of the two) in the general population. In our opinion, this conclusion is not justified, since affective disorders are clearly very much more common in the community than both of the other kinds of disorders and since the relation between the prevalences of schizoaffective disorder and schizophrenia/schizophreniform disorder in the general population is not known (and is hard to estimate because both conditions are rare). Therefore, the problem of whether schizoaffective disorder in a broad or in a narrow sense defines a distinct diagnostic category remains unsettled. However, schizoaffective disorder as well as psychotic affective disorders are linked with similar strength to nonpsychotic affective disorders.

The present family study backs up the conclusions drawn from follow-up studies of similar proband groups. Coryell et al. (24, 25) found that diagnostic distinctions between schizophrenia-type and affective-type symptoms and distinctions by temporal dissociation between psychotic and affective symptoms were most consistent and represented strong predictors of sustained delusional outcome. In contrast to the present and other family studies, follow-up studies lend only limited support to the validation of the distinction between unipolar and bipolar subtypes (26).

CONCLUSIONS

Differences in familial loading for schizophrenia, schizophreniform disorder, and schizoaffective disorder are one reason to keep schizoaffective disorder and mood disorders with incongruent psychotic features as separate diagnostic groups. However, since these differences are modest and more of a quantitative than of a qualitative nature, it is hard to accept that the boundary between these two diagnostic groups represents the demarcation line between the two major *DSM-III-R* diagnostic categories of schizophrenic and mood disorders. It is noteworthy in this context that only probands with definite mood-incongruent psychotic features and schizoaffective disorder or mood disorder with incongruent psychotic features were included. Consequently, the failure to find a stringent delineation between the diagnostic categories with regard to their familial loading cannot have been due to probands with uncertain diagnoses. The view that *DSM-III-R* schizoaffective disorder and *DSM-III-R* psychotic affective disorders are located on a continuum ranging from schizophrenic to nonpsychotic mood disorders is, therefore, more appropriate than allocating them to two distinct nosological entities. Alternatively, the two diagnostic groups under study might indicate two subtypes of a broadly defined concept of schizoaffective disorder representing a separate diagnostic category located between schizophrenia and affective disorders, as has been proposed by the RDC.

It is beyond the scope of this article to evaluate a third alternative view: the difference between the two *DSM-III-R* diagnoses under study might be due to differences in the qualifying conditions. Only conditions that cross-sectionally reveal a full schizophrenic syndrome qualify for *DSM-III-R* schizoaffective disorder if the exclusion criteria and temporal requirements are ignored. *DSM-III-R* mood disorders with mood-incongruent psychotic features may fail to fulfill the criteria for a full-blown *DSM-III-R* schizophrenic syndrome. Therefore, a plausible explanation of our results might be that the more similar a proband's psychopathological syndrome is to schizophrenia (cross-sectionally), the closer will be the familial link to schizophrenia, irrespective of the temporal overlap with affective syndromes.

Besides the reevaluation of the Iowa 500 study by Kendler et al. (7), this family study is the second in the literature to test the subdivision of the *DSM-III-R* categories of schizoaffective disorder and psychotic affective disorders by the unipolar/bipolar dichotomy. Both studies agree that this subdivision is a valid one; elevated rates of bipolar conditions are found only if the probands belong to a bipolar group. We are further in agreement with the reevaluated Iowa 500 study; in both reports *DSM-III-R* bipolar schizoaffective disorder is as closely linked to schizophrenia by familial risk figures as is unipolar schizoaffective disorder. In contrast to this conclusion, studies exclusively relying on the RDC suggest that bipolar schizoaffective disorder—but not unipolar schizoaffective disorder—is more a variant of affective than of schizophrenic disorders (23). The requirement in *DSM-III-R*, but not in the RDC, that schizoaffective disorder must meet the cross-sectional criteria of a full-blown schizophrenic syndrome at one time might explain these discrepant results.

Reliability of Best-Estimate Diagnosis in Genetic Linkage Studies of Major Psychoses: Results From the Quebec Pedigree Studies

Michel Maziade, M.D., Marc-André Roy, M.D., Jean-Pierre Fournier, M.D.,
Denis Cliché, M.D., Chantal Ménéte, Ph.D., Chantal Caron, M.D., M.Sc.,
Yvon Garneau, M.D., Noël Montgrain, M.D., Christian Shriqui, M.D.,

Objective: Diagnostic classification and reliability are critical in genetic linkage studies of schizophrenic and bipolar disorder. To establish an optimal diagnostic procedure, the authors drew 13 methodological elements from 38 major linkage studies and workshop reports. They determined reliability for a consensus best-estimate diagnostic method based on these 13 features. **Method:** Each of 59 subjects from several large multiplex pedigrees, densely affected by either schizophrenia or bipolar disorder, received a best-estimate diagnosis from unblind diagnosticians in the field and also from a panel of four research psychiatrists who were blind to the proband's and relatives' clinical status. The best estimate was based on personal diagnostic interviews, all available medical records, and family history data. **Results:** The diagnostic concordance between the field team and the blind psychiatric board yielded 78% to 90% agreement for the whole sample ($\kappa=0.83-0.88$) and 71% to 87% agreement for the subjects given field diagnoses ($\kappa=0.76-0.83$). The diagnoses made by the unblind field diagnosticians were biased toward a greater severity (or certainty) level in the diagnostic hierarchy (schizophrenia or bipolar) and more consistency with the most prevalent diagnosis affecting the pedigree. **Conclusion:** Since several previous linkage studies used diagnoses made by diagnosticians who were not blind to the status of the probands and the relatives or did not use a consensus best-estimate diagnosis, further reliability studies of different aspects of the best-estimate method and of its effect on linkage studies are needed. Such research is imperative given the serious impact of diagnostic misclassifications on genetic linkage results.

(Am J Psychiatry 1992; 149:1674-1686)

The linkage studies searching for a genetic marker for schizophrenia or bipolar disorder have yielded inconsistent results. Differences in diagnostic methods

and reliability are assuredly a major source of discrepancies between findings (1-4 and unpublished 1989 paper by T. Reich). Heterogeneity in the genetic etiology of the disorders, sampling differences, and difficulties in detecting phenocopies are additional causes for the differences in findings.

In the present paper we 1) review the previous major reports of linkage studies in terms of the diagnostic procedures in use, 2) derive methodological priorities from these prior works, 3) describe the best-estimate diagnostic method used in the Quebec pedigree studies, and 4) provide reliability data on our procedure.

PREVIOUS STUDIES

We reviewed 38 major studies published since 1980 and report on the presence or absence of findings of linkage between either schizophrenia (16 studies) or bi-

polar disorder (22 studies) and different genetic and biological markers. The main finding from this review is the striking discrepancies between reports in terms of the diagnostic methods or, more commonly, the lack of details about these procedures, even in the most recent reports. This lack of detail often makes comparisons of procedures between studies very difficult and is inevitably due to the fact that several of these studies were designed before the development of the current tighter and more comprehensive epidemiological procedures (5-7). Tables 1 and 2 compare the studies according to 13 characteristics of the diagnostic methods that current psychiatric epidemiology (3, 5-7, Reich) now recognizes as essential: specific diagnostic criteria, use of best-estimate diagnosis, type of structured interview, family history, use of medical records, involvement of several diagnosticians, independence of diagnosticians, blindness of interviewer, blindness of final diagnosis to genetic marker, blindness to proband's diagnosis, blindness to family relationship, reliability checks, and uniformity of methods for all subjects.

First, most linkage studies of the last decade used the Research Diagnostic Criteria (RDC), and only recently have *DSM-III* criteria been used. The data suggest that the broader RDC diagnoses are 20% to 30% more inclusive than the narrower *DSM-III* criteria, at least for schizophrenia (55). There are also striking differences between reports in the use of a best-estimate method of diagnosis, blindness to proband's and relatives' diagnoses, the use of several independent diagnosticians, repetitive reliability checks, degree of certainty on diagnosis, and, most of all, inclusion of less definite or severe diagnoses in the first hierarchical (or certainty) level for entry in the linkage analysis. Table 1 shows that the Amish study by Egeland and associates (16) is one of the few studies that paid attention to almost all these methodological considerations.

Only 11 studies (15, 21, 25, 26, 28, 31, 40, 42, 44, 48, 54) (tables 1 and 2) used a consensus best-estimate procedure (6, 7), i.e., a final diagnosis that was based on a personal structured interview, all available medical records, and structured information from several family respondents and that was generated by several diagnosticians who were not themselves the interviewers and who had no contact with the field work and therefore could be blind to the proband's and relatives' diagnoses, as well as to the index marker. The majority of reports did not indicate whether the diagnosticians were blind. Other studies used only personal interviews or used a best estimate only when there was a disagreement between the two first interviewers, who were often not blind to the proband's diagnosis. Furthermore, only one group (Amish study [16]) assessed reliability of diagnosis at the best-estimate level in addition to the structured-interview level. Incidentally, only a few studies assessed interdiagnostician reliability at the interview level (14, 29). The vast majority of publications do not mention reliability of diagnosis at any level. This is worrisome, since linkage analyses are notoriously influenced by diagnostic misclassifications (1, 2, 4, 56).

Only 15 reports (8, 9, 12, 13, 15, 19, 24, 25, 32, 33, 40, 42, 50, 52, 54) refer to blindness to genetic marker, and only nine refer to blindness to the diagnosis of probands (28, 42, 54) or relatives (15, 25, 28, 40, 42, 44). In most pedigree studies, the diagnosticians or interviewers had contact in the field with the family members and perforce could not be blind to the proband's and relatives' clinical status in such densely affected families. Besides, in several studies diagnosticians who had no contact in the field were nevertheless aware that only one disease (either schizophrenia or bipolar disorder) was under study by their group, and the impact on final diagnosis of this knowledge is unknown.

Having more than one diagnostician generating the final diagnosis minimizes the risk of undue influence caused by the idiosyncrasies of the diagnostic opinions of any particular diagnostician (16). According to the reports on the 38 studies, only 17 used more than one diagnostician. In addition, to avoid the immediate influence of others in making a decision, it is advantageous for each diagnostician to first make an independent best-estimate diagnosis before coming to a consensus with two or three other diagnosticians. Only eight studies relied on such an independence (9, 11, 15, 18, 25, 40, 44, 54). In several studies, the investigators sought to establish a consensus immediately at the beginning of the process (52). In other studies, diagnoses were made by trained persons reviewing the written information taken from the interview and a consensus best estimate was used only in case of disagreement between the first diagnosticians (or interviewers), who often were unblind (9, 13, 19). In some of the studies shown in tables 1 and 2, a first investigator reviewed the diagnosis done in the field and then a second investigator did a final analysis of all the information (21, 22, 31, 42).

Several of the studies did not use the same diagnostic procedure for all subjects, and the possible artifact created by this difference has so far received little attention. The biggest problem in comparing the results, however, as shown in tables 1 and 2, is that the definition of the diagnostic first hierarchical (or certainty) level that was entered into the linkage analysis varies from one study to another. Very few reports included only the most severe diagnosis, either definitive schizophrenia (34, 37-40, 47, 52, 54) or bipolar disorder (15, 26, 33), in hierarchical level 1. In most studies, schizoaffective or unipolar disorders were entered into level 1. The inclusion of a broader spectrum of disorders in level 1 raises the risk of introducing more heterogeneity.

PRESENT STUDY

The present 59 subjects were members of several large multiplex families that are densely affected by schizophrenia or bipolar disorder (57). The subjects were from different socioeconomic backgrounds, they were between 18 and 89 years old (mean=50.6 years, SD=17.7), and 25 (42%) were male. These pedigrees

were selected in eastern Quebec in the framework of our program of genetic epidemiology and molecular genetics of major psychoses. We integrated in the study design repetitive reliability assessments at different levels of the diagnostic procedure. We report here on one aspect of reliability: the concordance between two independent consensus best-estimate diagnoses, one blind and the other unblind to the diagnoses of probands and relatives, to prior clinicians' diagnoses, and to response to treatment.

Best-Estimate Method

We designed our field procedure, our blind best estimate by a psychiatric panel, and our reliability tests while considering the 13 methodological points mentioned previously.

Field procedure. The first home visit is performed by a research psychiatrist or a senior professional assistant, who explains the study and obtains consent. Through subsequent home visits, trained and clinically experienced professional interviewers administer the Structured Clinical Interview for DSM-III-R (SCID) (58) to which have been added a few modules of the Comprehensive Assessment of Symptoms and History (CASH) (53), especially those on the negative and positive symptoms of schizophrenia. This interview is audiotaped and the interviewers are blind to genetic markers, as are all the personnel working in the field. In addition, for each subject, at least two family respondents are interviewed through a structured family history interview composed of a list of 14 items. When an

item is rated positively, it refers to a checklist of symptoms corresponding to a *DSM-III-R* diagnosis (7). All available medical records are reviewed and edited to remove 1) identification of the subject, the treating physician, and the hospital, 2) past and current diagnoses by the clinicians, and 3) type of treatment and response to treatment. The last two are abstracted separately.

Then, under the supervision of the research psychiatrists in the field, the professional assistant highlights all the clinical information from the medical records that is pertinent to diagnosis and summarizes it, summarizes the personal interview and family history, and, still under the supervision of the field research psychiatrists (M.M., C.C., M.-A.R.), writes out a differential diagnosis while noting the presence or absence of each pertinent symptom and diagnostic criterion according to *DSM-III-R*, the RDC, and a clinical impression outside current classifications. After all possible information has been gathered, a consensus diagnosis (including a degree of certainty) for each episode and a consensus lifetime diagnosis are made by the field psychiatrists (M.M., C.C., M.-A.R.).

Blind psychiatric board procedure. A panel of four experienced and trained psychiatrists is kept blind to genetic markers, the proband's diagnosis (schizophrenia or bipolar disorder) and family relationships, prior clinicians' diagnoses, and response to treatment. The board is fed a complete diagnostic record consisting of edited raw clinical information—i.e., the audiotape (edited to keep the board blind) of the SCID interview in addition to the SCID ratings and notes made by the interviewer—photocopies of the edited original medical

lar depression; UPR=unipolar depression, recurrent episodes. An asterisk marks the hierarchical level in which linkage was present.

^fNot reported.

record notes, and data from structured interviews of family respondents (family history). Psychiatrist 1 reviews all this material, including the SCID audiotape, while psychiatrist 2 independently reviews all of this information except the audiotape. Separately they each make *DSM-III-R*, RDC, and clinical impression diagnoses. Then they discuss the case.

In case of complete agreement between psychiatrists 1 and 2, the complete diagnostic board record is presented at a board meeting and each symptom or diagnostic criterion (*DSM-III-R*, RDC) is reviewed systematically by the four psychiatrists, voted on, and rated before a final consensus diagnosis (with a certainty level) is rendered. The president of the board summarizes the discussion while emphasizing whatever areas of difficulty there were in reaching a consensus.

In case of a disagreement between psychiatrists 1 and 2, the SCID audiotape is sent to psychiatrist 2 and the complete diagnostic board record is forwarded to psychiatrists 3 and 4 before the board meeting. Again, each states an independent diagnostic opinion before the board meeting, during which the process previously described is then conducted.

Reliability Results

Table 3 presents the level of concordance between the consensus best-estimate diagnosis made in the field by two psychiatrists of the research team (M.M. or C.C. or M.-A.R.) with their experienced field interviewers and the one made blindly and independently by the board of four psychiatrists. When we used very strin-

gent criteria, i.e., also considered as a disagreement a discordance of one or two points on the certainty scale (1, definite diagnosis; 2, probable; 3, possible) for the same diagnosis, then a concordance rate of 78% was obtained for the whole sample ($\kappa=0.83$) and 71% ($\kappa=0.76$) was obtained for the 45 subjects who were given *DSM-III-R* diagnoses in the field. When only a difference in *DSM-III-R* diagnosis was considered as a disagreement, the concordance rose to 90% ($\kappa=0.88$) in the whole sample and 87% ($\kappa=0.83$) in the clinical sample. This is very satisfactory if compared to the reliability of the best-estimate procedure found in the study by Leckman et al. (6) ($\kappa=0.45-0.84$), in the Amish study (16) ($\kappa=0.68-0.95$), and in others (59) ($\kappa=0.63-0.82$).

All of the subjects who were found definitely normal by the diagnosticians in the field were also judged as such by the psychiatric board. Among the 45 subjects given *DSM-III-R* diagnoses according to the best estimate in the field, the board of psychiatrists arrived at a different conclusion for 13 subjects. However, for seven of these 13 subjects, the disagreements involved only the degree of certainty (definite, probable, possible) for the same diagnosis rather than a difference in *DSM-III-R* diagnosis. We found a statistically significant tendency of the field best estimates toward greater certainty levels and toward more consistency with the most prevalent disorder of the pedigree (either schizophrenia or bipolar disorder); this was true for 10 of the 13 total cases of disagreement (binomial exact test of $H_0=50\%$, $p<0.05$) and for all of the six disagreements on diagnosis (binomial exact test, $p<0.01$).

TABLE 3. Concordance Between Unblind Best-Estimate Diagnoses in the Field and Diagnoses Made by a Panel of Four Blind Psychiatrists for Subjects From Families Censely Affected by Schizophrenia or Bipolar Disorder

Sample and DSM-III-R Category	Cases of Disagreement		Cases of Agreement		Kappa	
	Total	Disagreement or Certainty ^a	Diagnosis Present	Diagnosis Absent	Disagreements on Diagnosis Only	Disagreements on Certainty Included ^b
Whole sample (N=59)	13	7	32	14	0.88	0.83
Subjects who received field diagnoses (N=45)	13	7	32		0.83	0.76
Affective spectrum	9	7	16	20	0.90	0.81
Bipolar I	5	3	10	30	0.85	0.80
Bipolar II	0		3	42	1.00	
Major depression					0.92	0.84
Single episode	2	2	2	41		
Recurrent	2	2	1	42		
Schizophrenic spectrum	4	0	10	31	0.71	0.74
Schizophrenia	1	0	10	34	0.77	0.77
Schizoaffective disorder	3	0	0	42	-0.03	-0.02
Alcohol dependence	0		3	42	1.00	
Other diagnoses	0		3	42	1.00	
Adaptation disorder	0		1	44	1.00	
Generalized anxiety disorder	0		1	44	1.00	
Delusional disorder	0		1	44	1.00	

^aOne- or two-point discordance on the certainty scale (1, definite=2, probable; 3, possible) on the same diagnosis, rather than disagreement on type of diagnosis.

^bKappa also considers as a partial disagreement a one- or two-point discordance on the certainty scale (1, definite; 2, probable; 3, possible) on the same diagnosis; weight given to difference on certainty scale: absolute difference of 0, weight=1; difference of 1, weight=2/3; difference of 2, weight=1/3; difference of 3, weight=0.

In addition to the seven disagreements on the certainty level of the same diagnosis, the differences in DSM-III-R diagnoses were the following. In the bipolar pedigrees, one schizoaffective depressive disorder (probable) diagnosed by the unblind team was diagnosed as a schizophreniform disorder (definite) by the panel, another schizoaffective depressive disorder (probable) was diagnosed by the board as schizophrenia (definite), one bipolar disorder (definite) was rediagnosed as schizoaffective disorder, and another bipolar disorder (definite) was rediagnosed as schizophrenia (probable). In the schizophrenia pedigrees, the one case of schizophrenia (definite) diagnosed by the unblind team was diagnosed by the board as organic mental syndrome (probable), and a schizoaffective disorder (probable) was rediagnosed as a bipolar disorder (definite). The concordance on severity of diagnosis, as determined by the Global Assessment Scale scores (60), was also satisfactory (intraclass correlation=0.82).

DISCUSSION

False positive or unreliable diagnoses might have a disastrous effect on the results of genetic linkage analysis of schizophrenia and bipolar disorder (1-4, 15, Reich). Our review of prior genetic linkage studies of schizophrenia and bipolar disorder shows serious discrepancies between studies in diagnostic methods. Paying attention to the 13 methodological points derived from this review should minimize diagnostic biases and improve the comparability of studies. In our present study we found a high reliability level with a consensus best estimate based on these 13 features.

However, whereas the presently observed concordance between an unblind best estimate made in the field and that made by a board of four blind psychiatrists could be considered as very satisfactory for other epidemiological purposes, it can have a strong impact on results of linkage studies, even more so because our results show that the unblind consensus best estimates made by the field team were biased toward a higher level of certainty or severity of diagnoses in the schizophrenia or bipolar spectrum and were also biased toward more consistency with the most prevalent diagnosis (either schizophrenia or bipolar disorder) in the respective multiplex pedigrees. In other words, unblind diagnosticians tended, for instance, to diagnose more affective disorders in bipolar pedigrees than the blind psychiatric board did. This finding is noteworthy if one considers that very few prior articles on linkage (see tables 1 and 2) reported complete diagnostician blindness to the proband's and relatives' diagnoses and that most groups were studying only one disorder (schizophrenia or bipolar) at a time, implying that the diagnosticians were aware of the familial disorder under investigation. Of course, the question of the exact origin of this field bias remains: Does it come from knowing in advance about the most prevalent disorder in the selected pedigrees, from being aware of the subjects' past diagnoses noted in the medical records by clinicians, or from knowledge of the subjects' response to treatment (i.e., neuroleptics versus antidepressants versus lithium)?

Schizoaffective diagnosis appears less reliable in the Amish study (16), where three of the seven diagnoses of schizoaffective disorder led to disagreements on the best-estimate diagnosis (kappa=0.71). So far, we have found disagreements for the three schizoaffective cases

in our sample. Similarly, Strober et al. (59) found a lower kappa (0.63) for schizoaffective disorders. However, in a large number of linkage studies (see tables 1 and 2) schizoaffective disorder was inserted in the first hierarchical level for analysis. The impact of this inclusion on results is unknown.

Our results call for further reliability studies of different aspects of the consensus best-estimate diagnosis in our sample and in others—for instance, the effect of editing material on the response to treatment, the concordance between diagnoses based on different sources of information, and the identification of the type of clinical cases that lead more often to disagreements on diagnosis. Our results also support our present, time-consuming effort to feed the board of blind psychiatrists with the edited raw clinical information from the interviews and medical records, instead of providing solely clinical material that has been sifted and abstracted by field interviewers or trained research assistants. The latter inevitably cannot be blind to the proband's and relatives' status while working with such densely affected pedigrees. Providing the board with raw clinical information and arranging to study simultaneously pedigrees affected by bipolar disorder and others affected by schizophrenia ultimately constitute the only way of keeping a board of diagnosticians really blind to the most prevalent disorder of these large multiplex pedigrees.

In conclusion, as clarified in recent meetings on psychiatric genetics (3, 4, Reich), any new genetic linkage study of major psychoses must include 1) the use of multiple diagnostic classifications because of the uncertain validity of any one set of criteria, 2) the use of several levels of certainty or severity in the diagnostic hierarchy, 3) the gathering of extensive clinical information, 4) a best-estimate procedure of diagnosis based on multiple sources of information, 5) blindness to the diagnoses of the proband and relatives, 6) follow-ups to establish stability of diagnoses.

To this list we suggest adding 1) the participation in the best-estimate procedure of two or more blind diagnosticians who are not at all involved in the data gathering, 2) an independent opinion by each blind diagnostician before a consensus with the others is reached, 3) repetitive reliability checks at the best-estimate level rather than only at the structured-interview level, since most of the time diagnosis is far from being based only on this latter source of information, 4) forwarding of edited raw clinical information to the blind panel of diagnosticians, rather than information already filtered, abstracted, or interpreted by unblind field investigators, and 5) simultaneous investigation by the board of blind diagnosticians of at least two different familial disorders (for instance, schizophrenia and bipolar disorder) so that the diagnosticians will be really blind to the proband's and relatives' diagnoses.

Most of all, our review again indicates that it is imperative that researchers enter only the most severe or definite diagnosis in the first hierarchical level for linkage analysis (1, 3, 4, Reich) and that publications pro-

vide a minimal description of the diagnostic procedure according to current standards in order to permit replication (61). Several of the most recent reports do not even provide this information. Finally, our results call for further studies of the impact and origin of this field bias on diagnosis in pedigree studies.

Combined Pharmacotherapy and Psychotherapy in the Acute and Continuation Treatment of Elderly Patients With Recurrent Major Depression: A Preliminary Report

Charles F. Reynolds III, M.D., Ellen Frank, Ph.D., James M. Perel, Ph.D., Stanley D. Imber, Ph.D., Cleon Cornes, M.D., Richard K. Morycz, Ph.D., Sati Mazumdar, Ph.D., Mark D. Miller, M.D., Bruce G. Pollock, M.D., Ph.D., A. Hind Rifai, M.D., Jacqueline A. Stack, M.S.N., Charles J. George, B.A., Patricia R. Houck, M.S.H., and David J. Kupfer, M.D.

***Objective:** The authors examined the rate of response to the combination of nortriptyline and interpersonal psychotherapy for acute and continuation treatment of elderly patients with recurrent major depression. **Method:** The subjects were 73 elderly patients, 61 of whom completed treatment. Nortriptyline steady-state blood levels were maintained at 80–120 ng/ml, and interpersonal psychotherapy was administered weekly for 9.1 weeks (median) of acute therapy and was decreased from biweekly to triweekly during 16 weeks of continuation therapy. During acute treatment nonresponding patients also received brief adjunctive pharmacotherapy with lithium or perphenazine. **Results:** Of the 61 subjects given adequate trials of nortriptyline and interpersonal psychotherapy, 48 (78.7%) achieved full remission (Hamilton depression rating of 10 or lower over 16 weeks of continuation therapy), 10 patients (16.4%) did not respond (Hamilton rating never below 15), and three achieved only partial remission (Hamilton rating of 11–14). Early versus late onset was not associated with a difference in response rate. During the placebo-controlled, double-blind transition to maintenance therapy, 19 (76.0%) of the 25 patients randomly assigned to placebo maintenance conditions showed continued recovery and six relapsed. None of the 24 patients assigned to nortriptyline conditions relapsed. **Conclusions:** Use of nortriptyline plus interpersonal psychotherapy for 9.1 weeks (median) of acute and 16 weeks of continuation therapy appears to be associated with good response and relatively low attrition but about a 25% chance of relapse during double-blind discontinuation of nortriptyline. These data require confirmation in a controlled clinical trial of acute and continuation therapy.*

(Am J Psychiatry 1992; 149:1687–1692)

The 1991 National Institutes of Health (NIH) Consensus Development Conference on the Diagnosis and Treatment of Depression in Late Life (1) highlighted the need for clinical trials assessing the efficacy

of combination pharmacotherapy and psychotherapy in the acute, continuation, and maintenance treatment of elderly patients with major depression, particularly those with recurrent illness. The published data are based on trials assessing the efficacy of a single intervention—either drug alone or psychotherapy alone but not both. Treatment success rates have been around 50%–70% in both drug (2, 3) and psychotherapy (4, 5) controlled trials enrolling older subjects with major depression, but many of these subjects were not truly elderly and most were outpatients. Also, most of these studies were relatively brief trials (generally 7 weeks or less) of acute therapy and the reports contain little information about the stability of therapeutic response during continuation therapy or about continued remission after drug discontinuation (6).

Received Nov. 27, 1991; revision received March 18, 1992; accepted April 17, 1992. From the Depression Prevention Clinic, Department of Psychiatry, University of Pittsburgh School of Medicine. Address reprint requests to Dr. Reynolds, Rm. E1135, 3811 O'Hara St., Pittsburgh, PA 15213.

Because of the need for information regarding the efficacy of combined therapy both acutely and during continuation therapy, we report here the first 2 years of experience in the University of Pittsburgh's Maintenance Therapies in Late-Life Depression study. The primary objective of the study is to assess the efficacy of maintenance nortriptyline and interpersonal psychotherapy (7) singly and in combination, under randomized, double-blind, placebo-controlled conditions, with respect to maintenance of recovery over a 3-year period after open-trial acute and continuation treatment of the index episode. Treatment of the index episode involves combined therapy with both nortriptyline and interpersonal psychotherapy under open-trial conditions. The investigators' choice of combination therapy for the non-experimental acute and continuation phases of the protocol (reported here) reflects the expectation that such an approach is likely to maximize the number of patients available for the subsequent experimental maintenance phase of the protocol. It also reduces the probability of bias on the part of patients and clinicians as to which treatment is likely to be most efficacious in the maintenance of recovery. It was required that a patient achieve remission and remain well for 16 weeks of continuation therapy (with both modalities) before random assignment to one of four maintenance therapies (medication clinic with placebo, medication clinic with nortriptyline, interpersonal psychotherapy plus placebo, and interpersonal psychotherapy plus nortriptyline). The investigators initially projected that 65% of the patients entering the protocol would meet the criteria for randomization, after remission of the index episode.

We provide in this report preliminary data on treatment success and stability of response, treatment failure, and attrition during combination acute and continuation therapy. We also report the rates of relapse during transition to maintenance treatment, where one-half of the patients are randomly assigned to placebo conditions under double-blind discontinuation conditions. We emphasize that the study is ongoing, with intake now at the halfway point, and that the data reported here are from an open trial complemented by placebo-controlled, double-blind discontinuation of nortriptyline. In light of the need for information about combination therapy identified by the 1991 NIH consensus conference (1), however, we believe that the results are sufficiently promising and instructive to warrant preliminary communication.

METHOD

Subjects

During the first 24 months of the study, 73 patients 60–80 years old (mean=67.5, SD=5.8) entered the protocol. The female/male ratio was 53/20; seven (9.6%) of the subjects were black, and 66 (90.4%) were white. The marital status distribution was as follows: widowed, N=29 (39.7%); married, N=27 (37.0%); divorced,

N=9 (12.3%); never married, N=5 (6.8%); remarried, N=1 (1.4%). The mean education level was 11.8 years (SD=2.4).

Approximately 48% of the subjects responded to media announcements, and 52% were referred through traditional medical channels. Approximately 243 subjects were screened in face-to-face interviews to yield the current group of 73 (a 30% yield). The patients were required to be experiencing at least the second lifetime episode of major depression (nonbipolar, non-delusional), to have a score on the 17-item Hamilton Rating Scale for Depression (8) of at least 17 after 14 days without psychotropic drugs, and to have had an interepisode wellness interval of at least 2 months but no longer than 2.5 years. Diagnoses were made by using the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (9) in an interview conducted by trained master's level psychiatric nurses and were confirmed in an independent interview by a senior faculty psychiatrist. Fourteen patients (19.2%) were diagnosed as having nonendogenous depression, 16 (21.9%) had probable diagnoses of endogenous depression, and 43 (58.9%) had definite diagnoses of endogenous depression. Twenty (27.4%) of the 73 patients reported that the first episode of major depression had occurred at age 60 or later ("late onset"), and 53 (72.6%) reported an earlier onset; the mean age at first episode was 47.5 years (SD=17.0). A review of past SADS-L diagnoses (definite) indicated the following rates: hypomania, 1.4% (N=1); panic disorder, 2.7% (N=2); generalized anxiety disorder, 5.5% (N=4); Briquet's disorder, 2.7% (N=2); alcoholism, 4.1% (N=3); drug use disorder, 1.4% (N=1); and phobic disorder, 2.7% (N=2). No patients met the criteria for cyclothymic personality, labile personality, antisocial personality, obsessive-compulsive disorder, or any psychotic disorders.

Forty-two percent of the patients (N=31) had major psychosocial problems requiring social service intervention. Twenty-five percent (N=18) required inpatient hospitalization during the acute therapy of the index episode, and 11.0% (N=8) had histories of suicide attempts. The median number of prior episodes of major depression was three. Upon entry into the protocol the 73 patients had a mean Hamilton depression rating of 22.3 (SD=3.8), a Beck Depression Inventory (10) score of 24.2 (SD=9.9), and a Global Assessment Scale (GAS) (11) score of 55.7 (SD=5.2). The mean duration of the index episode was 39.9 weeks (SD=35.8).

Almost all patients entering the protocol were under concurrent medical surveillance for chronic but stable (nonprogressive) medical disorders that did not contraindicate nortriptyline or require medications known to cause depression. Review of current medical status indicated the following frequencies of medical problems: cardiac, 41.1% (N=30); musculoskeletal, 39.7% (N=29); osteoarthritis, 30.1% (N=22); lower gastrointestinal, 32.9% (N=24); diverticulitis, 9.6% (N=7); upper gastrointestinal, 24.7% (N=18); fatal hernia, 17.8% (N=13); genitourinary, 39.7% (N=29); benign prostatic hypertrophy, 11.0% (N=8); vascular, 32.9% (N=24); hypertension, 20.5% (N=15); eyes, ears, nose,

and throat, 30.1% (N=22; cataracts, 12.3%; glaucoma, 5.5%); endocrine, 21.9% (N=16; thyroid, 9.6%; diabetes mellitus, 6.8%); neurologic (e.g., laminectomy, neurofibromatosis, and carpal tunnel syndrome), 13.7% (N=10); pulmonary, 15.1% (N=11; chronic obstructive pulmonary disease, 5.5%). Similarly, review of concurrent nonpsychotropic medications indicated the following rates of use: anti-inflammatory, 19.2% (N=14); endocrine, 13.7% (N=10); calcium channel blockers, 12.3% (N=9); diuretics, 15.1% (N=11); hormone replacements, 5.5% (N=4); β blockers, 6.8% (N=5); H_2 blockers, 5.5% (N=4); eye medications, 4.1% (N=3); theophylline, 1.4% (N=1).

Procedure

For the patients beginning treatment on an outpatient basis, acute therapy of the index episode consisted of combination nortriptyline and interpersonal psychotherapy, with weekly visits to the outpatient research clinic. Nortriptyline was prescribed by faculty psychiatrists in doses sufficient to produce a steady-state blood level of 80–120 ng/ml. The patients were instructed to take the full daily dose of nortriptyline at bedtime, and blood samples for determination of nortriptyline levels were taken 12–16 hours later. The blood levels were monitored weekly during acute therapy and biweekly to triweekly during continuation therapy. Interpersonal psychotherapy was delivered during weekly 50-minute sessions by experienced psychotherapists trained to, and maintained at, research levels of proficiency in interpersonal psychotherapy. All therapy sessions were audiotaped, and a random sample of 20% were rated for interpersonal psychotherapy specificity. Procedures for adapting interpersonal psychotherapy to use with elderly patients have been incorporated into a manual written by several of us (E.F., C.C., S.D.I., M.D.M., and C.F.R.).

A brief course of adjunctive pharmacotherapy (4–6 weeks), i.e., lithium (0.6–1.0 meq/liter), perphenazine (4–12 mg/day), or both, was permitted if the patient had not achieved full response after 8 consecutive weeks of nortriptyline at a therapeutic steady-state level (80–120 ng/ml). After a Hamilton rating of 10 or lower was achieved, adjunctive medication was discontinued. Unless the patient maintained a Hamilton rating of 10 or lower while receiving nortriptyline (alone) plus interpersonal psychotherapy, he or she could not enter continuation therapy.

A patient entered continuation therapy after meeting two criteria: 1) a Hamilton depression rating of 10 or lower for 3 consecutive weeks and 2) a steady-state nortriptyline blood level of at least 50 ng/ml. The purpose of continuation therapy was to ensure stability of response for 16 consecutive weeks before random assignment to a maintenance therapy cell. The frequency of clinic visits decreased to every other week for the first 8 weeks of continuation therapy and then to every third week during the final 8 weeks, in anticipation of monthly visits during the 3-year experimental maintenance phase of the study.

At the end of continuation therapy, the patient was randomly assigned to one of the four maintenance treatments; there was a 50% chance of being assigned to a nortriptyline cell and a 50% chance of being assigned to a placebo condition. During the 4–6-week transition to maintenance treatment, the nortriptyline dose of the patients assigned to placebo was gradually tapered by 20%–25% weekly under double-blind conditions.

Analysis

The major outcome measure, treatment success, was defined as remission of depressive symptoms (Hamilton depression rating of 10 or lower) sustained over 16 weeks of continuation therapy, as required for random assignment to a maintenance therapy cell. Our choice of a Hamilton score of 10 or lower as indicative of remission in the elderly is consistent with the findings of Georgotas et al. (12). However, we also examined outcome by using the more stringent criterion of a mean Hamilton depression rating of 6 or less during the final two ratings (over 4 weeks) at the end of continuation therapy.

RESULTS

Attrition

Of the 73 patients enrolled, 12 (16.4%) were removed from the study during screening or acute therapy. The reasons for attrition were treatment refusal or noncompliance (N=8), intercurrent medical conditions contraindicating further use of nortriptyline (N=3), and spontaneous remission during the 2-week psychotropic-drug-free observation period before the start of acute therapy (N=1). Two additional patients were lost during continuation: one died of a myocardial infarction, and one left the study against medical advice. Thus, a total of 59 patients (80.8% of those entering the study) completed the acute and continuation trial of combination nortriptyline and interpersonal psychotherapy (at least 26 weeks of acute therapy in the case of nonresponders).

Treatment Response

Sixty-one patients (83.6% of those entering) completed acute treatment and were therefore considered to have had adequate trials. Of the 61 completers, 48 (78.7%) responded fully; an additional three patients had partial responses (Hamilton scores of 11–14). Ten of the 61 patients who completed acute treatment were nonresponders (Hamilton depression ratings of 15 or higher) after at least 26 weeks of acute treatment (mean=35.8, SD=19.4), representing a treatment failure rate of 16.4%. Thus, 65.7% of those who entered and 78.7% of those who had adequate exposures to treatment could be considered treatment responders according to a criterion of a Hamilton score of 10 or less. Ac-

TABLE 1. Treatment Characteristics and Depression Scores for Elderly Depressed Patients Who Did or Did Not Respond to Combined Nortriptyline and Interpersonal Psychotherapy

Group and Time	Time From Intake (weeks)		Nortriptyline Dose (mg/day)		Nortriptyline Blood Level (ng/ml)		Hamilton Depression Score ^a	
	Mean	SD	Mean	SD	Mean	SD	Mean	SD

^a17-item Hamilton Rating Scale for Depression.

cording to the more stringent criterion of a Hamilton score of 6 or less, 56.2% of those who entered and 67.2% of those who received adequate trials would be considered responders (N=41).

Age at first episode (≤ 60 or ≥ 60 years) was not specifically associated with rate of treatment success. Of the 20 late-onset patients, 14 (70.0%) responded fully, and of the 53 early-onset patients, 34 (64.2%) responded fully.

Among the 51 patients with full or partial responses were five patients (9.8%) who relapsed during continuation therapy (Hamilton depression rating of 17 or above) but were successfully restabilized for the 15-week period of symptomatic remission required for random assignment to a maintenance therapy cell. The 10 nonresponders included four patients who showed brief symptomatic remission but subsequently relapsed and could not be restabilized.

Of the 25 patients assigned to placebo maintenance conditions, six (24.0%) relapsed during double-blind discontinuation of nortriptyline. Three had been assigned to placebo plus maintenance interpersonal psychotherapy, and three had been assigned to placebo plus medication clinic. None of the patients assigned to continuation of full-dose nortriptyline (N=24) suffered a relapse during the double-blind 4–6-week transition to maintenance therapy (Fisher's exact test, $p=0.02$).

The nortriptyline doses and blood levels and the Hamilton depression scores before and during treatment are shown in table 1. The Hamilton scores showed a mean drop of 71.0% (SD=12.2%) in the full and partial responders versus 9.2% (SD=29.7%) in the nonresponders.

Treatment Variables

The median duration of acute treatment for the 51 patients who completed treatment was 9.1 weeks (range=2.7–37.3). For the group of full and partial responders the mean duration of acute treatment was 11.2 weeks (SD=7.8), and the median was 10.0 weeks (8.6 weeks for the full responders and 26.6 weeks for the partial responders). These calculations do not take into account the additional time needed to restabilize

the five patients who relapsed during continuation therapy.) An examination of cumulative response time indicated that 44 (72.1%) of the treatment completers (86.3% of the 51 total responders) entered the continuation phase by 17 weeks. The nortriptyline doses and steady-state blood levels are shown in table 1.

During acute therapy, 17 (33.3%) of the total responders received brief courses (4–6 weeks) of adjunctive lithium carbonate (0.6–1.0 meq/liter) or perphenazine (4–12 mg/day). Inpatients were more likely to receive augmentation therapy: 13 of 18 (72.2%). Remission had to be sustained, however, after discontinuation of adjunctive medication for a minimum of 3 weeks before the patient was entered into the continuation treatment phase of the protocol. Adjunctive lithium or perphenazine was not allowed during continuation therapy.

DISCUSSION

The rate of full response in this study (65.7% of enrolled patients and 78.7% of completers) obtained with a combination of pharmacotherapy and psychotherapy is encouraging, since the study group consisted of elderly patients with highly recurrent major depression and moderate to severe impairment. Furthermore, the observation that 67.2% of the treatment completers had Hamilton scores of 6 or less by the end of continuation therapy suggests that the majority of the successfully treated patients had few residual depressive symptoms, a problem frequently noted in clinical trials for late-life depression. Such a finding also suggests that lower expectations for the quality of response in the elderly may not be justified. The overall attrition rate (16.4%) compares favorably to rates of 24%–42% typically reported in geriatric clinical trials (2, 3, and unpublished 1991 report by L.W. Thompson and D. Gallagher-Thompson), and the low failure rate (16.4%) also compares favorably to rates reported in the literature (33%–40%).

Furthermore, we used a conservative definition of treatment success, one requiring stability of response (remission) for 16 consecutive weeks of continuation

therapy. Without such a requirement, the true clinical significance of "treatment success" is diminished. The mean reduction in Hamilton depression ratings, 71.0%, is also clinically meaningful. This concept is further supported by increases in GAS scores from 55.7 (SD=5.2) at study entry to 76.6 (SD=5.8) at the start of continuation therapy and to 82.3 (SD=5.5) at the end of continuation therapy.

The use of a double-blind, placebo-controlled design for the transition to maintenance therapy permits a further assessment of the stability of recovery. With a 4–6 week transition to maintenance and a 20%–25% reduction of nortriptyline dose weekly and concurrent introduction of placebo, 19 (76.0%) of 25 patients randomly assigned to placebo showed no evidence of relapse. The 24.0% relapse rate among the placebo patients (versus 0% relapse among the nortriptyline patients) suggests several possibilities: 1) the brittle nature of the response of some geriatric patients; 2) the possible need for a longer period of continuation therapy; 3) the need for a longer period for drug discontinuation, with a slower rate of drug withdrawal; and/or 4) a discontinuation effect of interpersonal psychotherapy in some patients.

These results, while promising, are based on the open-trial, uncontrolled phase of the larger study. By design, control groups (monotherapy with placebo, nortriptyline, or interpersonal psychotherapy) are not used during this phase, the purpose of which is to maximize the number of remitted patients available for the experimental maintenance phase (which uses random assignment, placebo control, and double-blind procedure). Hence, the current results must be viewed as preliminary, and generalization to clinical practice can be made only with caution. Furthermore, both phases of the protocol (open acute/continuation, controlled maintenance therapy) are being carried out in a treatment-intensive research clinic where patients are monitored very closely. The magnitude of nonspecific effects is difficult to estimate in the absence of a placebo control during the acute/continuation phase. Finally, it should be borne in mind that the study group consists of "young old" patients (60–80-year-olds) who are living in the community and have little functional impairment in activities of daily living, not medically frail "old old" who are institutionalized (13).

In a review of 25 double-blind antidepressant drug studies published between 1964 and 1986 that focused on patients over 55 years of age, Gerson et al. (2) concluded that "drugs are clearly superior to placebo; they show comparable therapeutic efficacy—about 50% improvement in Hamilton Psychiatric Rating Scale for Depression scores versus 20% to 25% on placebo." In perhaps the most rigorous study to date, Georgotas et al. (12) reported a rate of response (Hamilton rating of 10 or lower) of 60% for both nortriptyline and phenelzine versus a 13% response rate for placebo among depressed patients 55 years of age and older who were treated for 7 weeks. Georgotas et al. (14) also reported additional benefit from extending the antidepressant

medication trial past 7 weeks to 9 weeks. Addition of this 2-week period was associated with an increase in the response rate to 69%. A caveat would appear to be appropriate in interpreting these data on extending duration of therapy: if a trial goes on long enough, some patients may improve spontaneously.

The most extensive research experience with the psychotherapy of late-life depression was reported by Thompson et al. (4). These investigators reported a study of 91 elderly outpatients with a major depressive disorder (more than 50% with recurrent major depression) who were treated with 16 to 20 sessions of behavioral, cognitive, or brief psychodynamic psychotherapy. The authors used a 6-week delayed-treatment control condition and reported a 24% dropout rate overall. The major finding of the study was that "by the end of six weeks patients in the [active] treatment conditions showed improvement, whereas controls did not. Overall, 52% of the treatment sample attained remission by termination; another 18% showed significant improvement."

These studies using drug alone or psychotherapy alone for elderly outpatients with major, unipolar, non-delusional depression resulted in treatment success rates of 60%–70% at 6–9 weeks, versus 0%–13% for wait-list/control or placebo conditions. Our current experience of using combination nortriptyline and interpersonal psychotherapy has yielded a somewhat higher success rate (78.7% for the completers) and a dropout rate of only 16.4%, over an acute treatment period lasting a median of 9.1 weeks in all completers (range=2.7–37.3 weeks), in a somewhat older and medically more complicated population. Although this comparison might be viewed as evidence of the superiority of combined pharmacotherapy and psychotherapy, it is probably confounded by different durations of acute therapy (7–9 weeks for Georgotas et al. [12, 14], 6 weeks for Thompson et al. [4], and 2.7–37.3 weeks in the current study), the use of adjunctive medication in the current study, and possible differences in referral biases, portals of entry, subject inclusion/exclusion criteria, and definitions of outcome. More recently, Thompson and Gallagher-Thompson have reported an improvement rate of over 90% in elderly depressed outpatients (mean age=66.7 years) treated with combination desipramine and cognitive-behavior therapy over 6–10 months (unpublished 1991 report). In that study, "improvement" meant a reduction of symptoms great enough that the patient no longer qualified for a Research Diagnostic Criteria diagnosis of major depressive disorder. This success rate appears similar to ours (78.7%), except that their definition of "improvement" may have allowed greater residual symptoms.

Prospective, controlled clinical trials will be necessary to demonstrate the superiority of combination therapy over monotherapy in the acute/continuation treatment of major depression in elderly patients. Such a trial is indicated by comparison of the current preliminary results with published data from controlled trials assessing monotherapeutic interventions. In addition to their

possible clinical utility, such trials would possess clinical face validity by mimicking actual clinical practice and might illumine the possible synergy frequently hypothesized for combination therapy. The low dropout rate observed (16.4%) may partly account for the encouraging preliminary outcome here.

Religious Coping and Depression Among Elderly, Hospitalized Medically Ill Men

Harold G. Koenig, M.D., M.Sc., Harvey J. Cohen, M.D., Dan G. Blazer, M.D., Ph.D.,
Carl Pieper, D.P.H., Keith G. Meador, M.D., M.P.H., Frank Shelp, M.D.,
Veeraindar Goli, M.D., and Bob DiPasquale, M.S.

Objective: The investigators examined the frequency of religious coping among older medical inpatients, the characteristics of those who use it, and the relation between this behavior and depression. **Method:** The subjects were 850 men aged 65 years and over, without psychiatric diagnoses, who were consecutively admitted to the medical or neurological services of a southern Veterans Administration medical center. Religious coping was assessed with a three-item index. Depressive symptoms were assessed by self-rating (the Geriatric Depression Scale) and observer rating (the Hamilton Rating Scale for Depression). **Results:** One out of every five patients reported that religious thought and/or activity was the most important strategy used to cope with illness. Variables that were associated with religious coping included black race, older age, being retired, religious affiliation, high level of social support, infrequent alcohol use, a prior history of psychiatric problems, and higher cognitive functioning. Depressive symptoms were inversely related to religious coping, an association which persisted after other sociodemographic and health correlates were controlled. When 202 men were reevaluated during their subsequent hospital admissions an average of 6 months later, religious coping was the only baseline variable that predicted lower depression scores at follow-up. **Conclusions:** These findings suggest that religious coping is a common behavior that is inversely related to depression in hospitalized elderly men.

(Am J Psychiatry 1992; 149:1693-1700)

Medical illness that precipitates hospitalization is a stressful experience that can interrupt social and work routines, drain finances, separate families, reverse caregiver roles, and create situations of forced dependency. Physical illness also brings with it the threat of pain and long-term disability, disfigurement, the prospect of approaching death, and feelings of existential anxiety and sometimes despair. During physical illness coping resources are seriously tested and frequently overwhelmed, as evidenced by the fact that 40% or more of older hospitalized patients experience some form of clinical depression (1, 2). Religious beliefs and behavior, in turn, are prevalent among older persons (3,

4) and are reported to serve as a coping strategy to help manage emotional distress (5-8). The extent to which older medical inpatients use religion for this purpose, the characteristics of those who do so, and the effectiveness of this strategy are largely unknown.

National samples of Americans of all ages indicate that persons who find personal comfort and support from religion are more likely to be older, female, black, less educated, widowed, employed in manual or unskilled occupations, more economically deprived, and affiliated with conservative Protestant religious denominations (3). These sociological findings suggest that persons with fewer health, social, and financial resources, when facing situations over which they have little control (such as acute hospitalization), might turn to religion for solace.

Whether religious beliefs and behavior actually help to prevent or relieve emotional distress is far from clear. Psychiatric illness may be even more common among the religious (9-11), perhaps predisposing them to greater problems in later life when they are faced with the stress of physical illness and/or approaching death. Thus far, systematic research on the relation between religious coping and depression among older adults in

Received July 26, 1991; revision received Feb. 5, 1992; accepted March 19, 1992. clinical settings has been limited. Previous studies have been hampered by small sample sizes, less than rigorous sampling methods, and unequal sex distribution (few males) (6-8).

This report emanates from the Durham Veterans Administration (VA) Mental Health Survey (12, 13), a cross-sectional and longitudinal epidemiologic study of depression among hospitalized medically ill men. We examine religious coping, its sociodemographic and health correlates, and its relation to depression both cross-sectionally and over time. Four major questions guided this investigation: 1) How common is religious coping in this population? 2) Is this coping behavior more likely among those with fewer socioeconomic, physical, or mental health resources? 3) When other factors are controlled, is there an association between religious coping and depression? 4) If such a relationship exists, is it especially strong in any subgroup of the population, such as those with more severe medical illness, low social support, prior mental health problems, or other attributes?

METHOD

Between Sept. 1, 1987, and Jan. 1, 1989, all men aged 65 years and over who had been admitted to medical or neurological services at the Durham VA Medical Center were screened for depression. For inclusion in the study, patients were required to score 15 or higher on the Mini-Mental State examination (14) and to be physically capable of undergoing a psychiatric evaluation. Psychiatric patients were excluded. Patients were evaluated within 48-72 hours of admission by a social worker and/or a Fellow in geriatric medicine (H.G.K.).

Data were collected on demographic characteristics and social and economic resources, including age, race, education, prior occupation (15), retirement status, current living situation, marital status, yearly income, and social support. Social support was measured with a three-item index that explored size of the support network (16), frequency of interaction, and perceived adequacy of support (17) (values for each item ranged from 1 to 5; Cronbach's $\alpha=0.57$). Over 40 religious denominations were represented in the study group; these were categorized into nine general religious groups according to a schema provided by Rof and McKinney (18).

The physical health of the participants, including medical diagnoses, functional status, and cognitive status, was assessed. Functional status was determined by measuring physical (19) and instrumental (20) activities of daily living. Physical activities of daily living included bathing, dressing, toileting, problems with incontinence, transfer from bed to chair or vice versa, and feeding (each rated 0-2); instrumental activities of daily living involved ability to travel, shop, prepare meals, do housework, and handle finances (rated 0 or 1). These two types of ratings together produced an 11-item scale with a possible range of scores from 0 (low functioning)

to 17 (high functioning). As we have mentioned, cognitive status was measured with Mini-Mental State examination scores, which ranged from 15 to 30.

The assessment of mental health included information on alcohol use, prior psychiatric problems, and family history of psychiatric problems. Depression was assessed by self-rated and observer-rated scales. The self-rated 30-item Geriatric Depression Scale (21) was administered by the social worker to all patients; this scale has been validated as a measure of depression in older medical inpatients (22). The men aged 70 years and older were also assessed by one of us (H.G.K.) with the Hamilton Rating Scale for Depression (23), a measure used in other studies of the elderly (24) and medical inpatients (25). Depression scales were administered early in the interview, before the assessment of religious coping.

Religious coping was assessed with a three-item index. Each item measured how much the patient relied upon religion to help manage the emotional stress associated with his illness. In item 1, the patient was asked an open-ended question about how he coped. This item was chosen in order to identify the coping behavior that the patient himself felt was most helpful, and the question was asked before questions on religion that might bias responses. If the response was religious in nature (e.g., faith in God or Jesus, prayer, church), the patient received a score of 10; if the spontaneous response was not religious (e.g., stay busy, family support), a score of 0 was assigned. A value of 10 for religious responses was chosen in order to give this item equal weight with the others in the index.

In item 2, patients were asked to rate on a visual analog scale the extent to which they found religious beliefs or activities helpful in coping with their situation. The scale was numbered from 0 ("not much or not at all") to 10 ("the most important thing that keeps me going"). In approaching patients with the rating scale, the investigators allowed patients to define for themselves the meaning of the term "religion" but made clear that this could involve personal belief alone or include religious activity such as prayer or church attendance.

In item 3, the interviewer rated the patient on a scale of 0-10 on the basis of an overall assessment of how much the patient used religion to cope. This judgment was based on the patient's further elaboration on religious coping themes during answers to items 1 and 2 and on a separate discussion about how religion was helpful. The scores from the three items were then summed, and an index with values ranging from 0 to 30 was obtained. Cronbach's α (reliability) for the index in the overall sample ($N=850$) was acceptable (0.82).

Test-retest/interrater reliability for the religious coping index was also determined for a subgroup of 188 consecutively admitted men. The religious coping index was administered twice to these patients, each time by a different rater; ratings were separated by 12-36 hours. The Pearson correlation between scores obtained on the religious coping index at the two administrations was 0.81. The interrater agreement for the ob-

server-rated religious coping item (item 3) was surprisingly high (Pearson's $r=0.87$) given that the raters came from markedly different religious backgrounds (secular humanist versus conservative Protestant).

All participants in the baseline study who were readmitted to the medical or neurological services during the 16-month study period and 5 months thereafter (designated "time 2") were reevaluated by the social worker with the Geriatric Depression Scale and the religious coping index. Again, psychiatric admissions were excluded. If more than one readmission occurred, the results from the last interview during the 21-month observation period was used for time 2. This provided information on change in depressive symptoms and religious coping over time among patients whose medical illness prompted rehospitalization during the project.

Analyses were performed with the SAS statistical package (26). Simple statistics were used to determine the frequency of spontaneously reported, self-rated, and observer-rated religious coping. Bivariate relations of covariates with religious coping (religious coping index score) and depression (Geriatric Depression Scale and Hamilton depression scale scores) were examined with Pearson correlations. Hierarchical regression was used to examine the strength of relationships, controlling for the effects of other covariates.

To determine whether patients who used religious coping had fewer socioeconomic or health resources than other patients, the religious coping index score was regressed on a series of 16 demographic, socioeconomic, and health variables (excluding depression). A backward stepwise regression method was used to eliminate nonsignificant variables ($p>0.05$); missing values were dealt with by listwise deletion. The regression was performed in five stages. In the first stage, demographic variables (age, race, and occupational and retirement status) were entered into the model. In subsequent stages, religious affiliation, socioeconomic resources, and mental and physical health variables were added. The fifth stage produced a final model that contained the significant correlates.

We examined the relation between depression and religious coping in the following manner. First, a model for depressive symptoms was constructed by regressing it on the 15 sociodemographic and health variables (excluding religious variables). Once a final model had been obtained, we added religious coping and religious affiliation variables. Interactions between religious coping and all other variables in the model were tested and included in the final model if alpha was less than or equal to 0.05. Regression models were developed for both self-rated symptoms (Geriatric Depression Scale) and observer-rated symptoms (Hamilton Rating Scale for Depression).

We analyzed the longitudinal data as follows. Pearson correlations determined bivariate relations between baseline (time 1) group characteristics and follow-up (time 2) Geriatric Depression Scale score. Hierarchical regression was then used to assess the relation between time 1 religious coping index score and time 2 Geriatric Depression

Scale score, controlling for time 1 Geriatric Depression Scale score and other significant baseline correlates.

RESULTS

There were 1,110 consecutively admitted new patients during the study period. Eight hundred fifty men (77%) underwent comprehensive social, psychological, and physical health examinations; 260 did not participate because of advanced dementia or delirium (12% with Mini-Mental State scores less than 15), communication problems (2%), refusal or discharge before being seen (5%), or other reasons (4%). Nonparticipants were more likely to be older, black, and residents of nursing homes and to have diagnoses of neurological or respiratory illness.

The sociodemographic and health characteristics of the subjects are presented in table 1. The distributions of race, marital status, and medical diagnoses were similar to those among elderly male patients discharged from VA hospitals in District 8, which covers most of North Carolina and parts of Virginia, Kentucky, Tennessee, and South Carolina (12). Table 2 presents the

religious affiliations of the participants. The distribution was comparable to that of elderly men living in central North Carolina; compared to the population of the nation as a whole, however, a disproportionate number of men came from conservative or black Protestant denominations (63% in this study, 54% in central North Carolina, and 17% nationally).

In response to the open-ended question directed at how they coped, 20% (N=167) of the subjects (24% of those aged 70 years and over) spontaneously replied that religion was a primary factor. Religion in this sense typically involved having trust or faith in God, praying, reading the Bible or other religious literature, listening to religious programs on the radio or watching religious programs on television, participating in church services or other related activity, and receiving emotional support from church members or a pastor. On the visual analog scale, which ranged from 0 to 10, the mean rating by patients was 6.5 (SD=3.1). More than half of the subjects (56%, N=471) rated themselves 7.5 or higher, and 21% gave themselves a rating of 10 (religion being "the most important thing that keeps me going"). Observer ratings of religious coping for the group ranged from 0 to 10, with a mean 5.7 (SD=3.2). The religious coping index scores for the group ranged from 0 to 30; the mean was 14.3 (SD=8.7).

Sociodemographic and Health Correlates of Religious Coping

The bivariate relations of covariates to religious coping are presented in table 3 (column 1). Race, retirement status, social support, family history of psychiatric problems, and alcohol use were significant correlates. Liberal Protestants, Catholics, and patients with no affiliation were less likely to use religious coping (negative correlations), whereas black Protestants and members of fundamentalist/evangelical groups were more

^aRegression analysis was performed in five stages; this table represents the fifth and final model (model $F=9.5$, $df=15$, 810, $p\leq 0.001$; total $R^2=0.15$).

^bBetas are standardized; for every 1 standard deviation change in the independent variable there is a beta standard deviation change in religious coping, with all other variables in the model controlled.

^c $p\leq 0.001$.

^d $p\leq 0.05$.

^eDummy variables were created to represent each religious group and were then compared to variables for patients with no religious affiliation (partial $F=7.8$, $df=8$, 828, $p\leq 0.001$).

^f $p\leq 0.01$.

likely to use religious coping than were members of other religious groups.

Using hierarchical stepwise regression, we examined the relations between religious coping and sociodemographic and health characteristics. In stage 1, age, race, education, and occupational status were entered as independent variables into a model with religious coping index score as the dependent variable. In stages 2 through 5, religious affiliation, social/economic resources, and mental and physical health variables were added successively to the model. At each stage, nonsignificant variables were excluded by using backward stepwise elimination. Variables unrelated to religious coping and thus dropped from the model were education and occupational status (stage 1), living situation, marital status, and income (stage 3), family history of psychiatric problems (stage 4), and functional status and medical diagnosis (stage 5). The fifth and final model is presented in table 4.

Religious affiliation accounted for the largest proportion of explained variance (46%). Men from conservative, black, and fundamentalist Protestant denominations were especially likely to use religion to cope. Demographic variables (age, race, and retirement status), social support, and mental health variables (history of psychiatric problems and use of alcohol) each accounted for about 15% of the explained variance in religious coping. Patients who were older, were black, had a history of psychiatric problems, and reported greater social support were more likely to use religion

as a coping behavior. Patients who used alcohol, on the other hand, were less likely to do so. The only physical health factor related to religious coping was cognitive status, which accounted for about 8% of the explained variance. Contrary to expectation, there was no significant relation between religious coping and functional status or medical diagnosis.

Religious Coping and Depression

Bivariate analyses indicated inverse correlations between religious coping index scores and both self-rated and observer-rated depression scores (Geriatric Depression Scale score, $r=-0.16$, $p\leq 0.001$; Hamilton depression score, $r=-0.14$, $p\leq 0.01$). We then used hierarchical regression to control for the confounding effects of other sociodemographic and health correlates of depression. Stepwise procedures were used to construct two models for depression (Geriatric Depression Scale scores and Hamilton depression scores as dependent variables). Fifteen sociodemographic and health variables (excluding religion) were examined as possible correlates of depression in each model.

In the development of the Geriatric Depression Scale model, variables unrelated to Geriatric Depression Scale score and thus eliminated were marital status, retirement status, occupational status, income, education, and living situation. Variables included in the final model were age, race, social support, history of psychiatric problems, family history of psychiatric problems, alcohol use, cognitive status, functional status, and six medical diagnoses (respiratory disease in particular [13]) (model $F=20.7$, $df=14$, 807, $p\leq 0.001$; $R^2=0.26$). Religious affiliations were then added but did not contribute significantly (partial $F=0.8$, $df=8$, 799, $p>0.50$). Finally, religious coping index score was added to the model, yielding a partial F of 19.8, $df=1$, 799, $p\leq 0.001$ (table 5, first column). The inverse relation between religious coping and depressive symptoms was stronger among men who had more severe disability (partial $F=3.9$, $df=1$, 798, $p\leq 0.05$). Religious coping index score did not interact significantly with any other correlates of depression, although the relation between religious coping index score and depression did tend to be stronger in men who had a prior history of psychiatric problems (partial $F=3.3$, $df=1$, 797, $p=0.07$).

We then examined the relation between religious coping index score and observer-rated depressive symptoms (in men aged 70 years and over). A model of significant correlates of Hamilton depression scale score was created (religious factors excluded). Variables related to Hamilton depression score and controlled for in the model were social support, history of psychiatric problems, alcohol use, and functional status (model $F=15.0$, $df=4$, 318, $p\leq 0.001$; $R^2=0.16$). The addition of religious affiliations contributed significantly to the model—largely a result of inverse associations between Hamilton depression scale score and moderate Protestant and Catholic affiliations. Finally, religious coping index score was added; it was inversely correlated with

Hamilton depression scale score (partial F=12.2, df=1, 306, p<0.001) (table 5, second column). There were no significant interactions between religious coping index score and other variables in the model.

Follow-Up Phase

In the follow-up phase, 256 (30%) of the 850 participants were readmitted to the hospital one or more times during the 16-month study and 5 months thereafter. Of these patients, 202 (79%) received complete follow-up evaluations, including both Geriatric Depression Scale and religious coping index assessments. The time from index hospitalization to readmission evaluation ranged from 0 to 20 months (mean=6 months). Compared with the 850 participants in the baseline study, readmitted patients were more likely to have a diagnosis of cancer (33% versus 22%) and less likely to have neurological disease (7% versus 14%); otherwise, they were similar in all other sociodemographic and health characteristics. The overall mean changes in both religious coping index score and Geriatric Depression Scale score (time 1 to time 2) were small (1 point or less). There was no relation between change in religious coping index score and change in depressive symptoms (Pearson's $r=0.06$, $p=0.45$).

Baseline predictors of time 2 Geriatric Depression Scale

TABLE 6. Follow-Up (Time 2) Geriatric Depression Scale Score Regressed on Baseline (Time 1) Religious Coping Index Score, With Other Baseline Predictors Controlled, for 202 Elderly Male Medical Inpatients

Variable ^a	Beta ^b
Time 1 Geriatric Depression Scale score	0.62 ^c
Medical diagnosis	
Cancer	-0.06
Gastrointestinal disease	-0.06
Neurological disease	-0.04
Respiratory disease	-0.08
Renal disease	0.15 ^c
Cardiovascular disease	-0.11
Time 1 religious coping index score	-0.18 ^e

^aFourteen baseline variables were not significantly related to time 2 Geriatric Depression Scale score and were dropped from the model. Dummy variables were created for each medical diagnosis; the missing category was other medical diagnoses. For medical diagnoses in the model: partial F=2.1, df=6, 196, p<0.05 (model F=20.0, df=8, 193, p<0.01; total R²=0.45).

^bBetas are standardized; for every 1 standard deviation change in the independent variable (e.g., time 1 religious coping index score), there is a beta standard deviation change in time 2 Geriatric Depression Scale score, with all other variables in the model controlled. For time 1 religious coping index score, SD=8.7; for time 2 Geriatric Depression Scale score, SD=5.8.

^cp<0.001.

^dp<0.05.

^ep<0.01.

score were then examined. Bivariate analyses demonstrated significant correlations between time 2 Geriatric Depression Scale score and time 1 Geriatric Depression Scale score ($r=0.64$), social support ($r=-0.16$), functional status ($r=-0.20$), diagnosis of renal disease ($r=0.15$), and time 1 religious coping index score ($r=-0.24$). To control for confounding, hierarchical stepwise regression was again used (table 6). Time 1 Geriatric Depression Scale score was entered first into the model, followed by 15 other predictors, with time 1 religious coping index score entered last. The final model contained three variables that predicted 45% of the variance in time 2 Geriatric Depression Scale score: time 1 Geriatric Depression Scale score, six medical diagnoses (renal disease in particular), and time 1 religious coping index score. No interactions between variables in the final model were significant. Thus, religious coping was the only baseline variable that predicted lower depression scores on follow-up (partial F=10.4, df=1, 193, $p=0.002$).

DISCUSSION

We found that religious beliefs and behavior were commonly used to manage stress in this medically ill group of older adults. When asked how they coped with their situations, 20% of the men spontaneously gave a response involving religion. Patients reported that trust or faith in God, prayer, Bible reading, and strong church relationships gave them comfort and a feeling of peace. We recognize that this finding may be in part due to the nature and location of our sample (southern VA

hospital). A relatively high proportion of these patients were affiliated with conservative or black Protestant groups, whose traditions place strong emphasis on religion as a source of comfort in times of stress. The high rate documented among this all-male study group, however, is notable because religious coping is generally more common among women than men (3, 28), suggesting that this behavior might be even more prevalent in hospital samples that include women.

What are the characteristics of men who use religion to cope? Do they experience greater stress than other patients? Do they possess fewer socioeconomic or physical or mental health resources? In general, this was a group of older patients who had relatively severe medical illnesses, often advanced functional disabilities, low educational levels (the majority with less than a high school education), and yearly incomes averaging less than \$10,000. The high rate of religious coping in this population, as we have discussed, suggests that it may indeed be characteristic of those with fewer coping resources. Within this group, however, there was no association between religious coping and level of functional disability, income, education, or previous occupation. On the other hand, religious coping was more common among those who were older, were black, or reported prior psychiatric problems—patients who may be more vulnerable to psychosocial or health stressors.

Furthermore, the strongest correlate of religious coping was religious affiliation (conservative, black, and fundamentalist/evangelical Protestant groups). This association by itself may have socioeconomic and health implications. The Piedmont Epidemiologic Catchment Area study showed that older members with these affiliations were more likely to come from lower socioeconomic classes, have lower educational levels, and have more chronic health problems and physical disabilities (27). Because these affiliations encourage affective release and emphasize religion as a source of comfort to those who are suffering, they may draw socioeconomically deprived or physically impaired elders into their congregations.

Some correlates of religious coping suggest mechanisms by which this behavior may help reduce stress and facilitate adaptation. Religious coping was positively related to both high level of social support and avoidance of alcohol, factors which in a VA hospital population could help to protect against emotional illness. Social support was one of the strongest inverse correlates of depression in these subjects (12). Religion may enhance social support by providing contacts with age-matched peers and/or by encouraging the development of supportive relationships within the religious community. In a study of older medical outpatients in Springfield, Ill., more than one-half of the subjects indicated that nearly all of their five closest friends came from their church congregations (4). For older black persons in particular, the church is reported to be a major source of informal social support (29).

Although many older men claimed that religion was helpful in coping with their illness, is there any evidence

to substantiate these reports? We found religious coping to be inversely related to depression, whether assessed by self-report (Geriatric Depression Scale) or by clinician rating (Hamilton Rating Scale for Depression). This relationship was stronger among men who were more functionally disabled, and tended to be so among patients who reported histories of psychiatric problems. Note that these were also the groups who were the most depressed. Other investigators have similarly found an inverse correlation between religious cognition/behavior and depression in physically ill elders (30, 31) and those with psychiatric illness (32, 33). Thus, these findings provide further evidence that religious coping behavior is especially helpful to older patients with few other physical or emotional resources. Studies have shown that when older persons are in situations over which they have little control, religious beliefs and behavior may counteract feelings of helplessness, provide meaning and order to experiences, and give back a sense of control (34, 35).

An alternative explanation for the inverse relation between depression and religious coping is that as depression worsens, religious faith weakens. Depressed, physically ill persons may lose interest in religion (just as they do in other aspects of life) or may become angry at God for their poor health and dismal situation. Our data, however, provide little support for this explanation. In the follow-up portion of the study, religious coping did not decrease as depressive symptoms increased. If anything, increasing depression tended to be associated with increases in religious coping ($r=0.06$, n.s.). Thus, our data and those of others (36, 37) indicate that when changes in religious coping occur during a period of increasing emotional stress in the context of physical illness, there is no decline in religious coping behavior.

Furthermore, in the longitudinal phase of our study, the baseline religious coping index score was the only sociodemographic or health variable that predicted lower depression scores on follow-up. Although the strength of the relationship was only modest, this finding provides additional evidence that the inverse relation between religious coping and depression in our cross-sectional study might have been due to a buffering effect of religious coping on depression, rather than to an inimical effect of depression on religious coping.

In this study, religious coping was measured with an index made up of both self-rated and observer-rated items. Religion was not defined, other than to say that it might include either belief or activity. However, religion was interpreted as Judeo-Christian by virtually all participants in the study. While this made assessment easier and allowed for high interrater reliability (Pearson's $r=0.81$) on the religious coping measure, it limits the generalizability of these results to religious cognition and behavior in the Judeo-Christian tradition.

Our finding of a high frequency of religious coping among older medical inpatients should alert consultation-liaison psychiatrists and nonpsychiatric health care providers to such behavior and to the possibly use-

ful function it may serve. For elderly persons with health problems and stressful life situations, the immediate aim of psychotherapy is often to support healthy coping behavior (38). Thus, knowledge of strategies that older persons use and find effective in facilitating adjustment is essential. Furthermore, because clinicians may play a role in controlling access to chaplains, religious reading materials, and religious services, identification of patients who rely heavily on religion as a coping behavior is necessary in order to direct resources appropriately.

The inverse relation between religious coping and depression documented here, while only moderate in strength, nevertheless has clinical importance because coping behavior is changeable and, unlike other health variables, can be affected by psychotherapeutic strategies. Religious cognition and behavior may be especially helpful to older patients with severe functional disability and in other situations where a sense of control is lost and other resources are limited. We recognize, however, that while the results of the present study are suggestive, only an intervention trial can definitively establish that religious behavior either prevents or relieves depression in this setting.

Visual Hallucinations in Patients With Macular Degeneration

Suzanne Holroyd, M.D., Peter V. Rabins, M.D., M.P.H., Daniel Finkelstein, M.D., Marie C. Nicholson, R.N., Gary A. Chase, Ph.D., and Sally C. Wisniewski, B.A.

Objective: This study was undertaken to determine the prevalence of visual hallucinations in patients with macular degeneration, describe such hallucinations phenomenologically, and possibly determine factors predisposing to their development. **Method:** Using a case-control design, the authors screened 100 consecutive patients with age-related macular degeneration for visual hallucinations. Each patient with visual hallucinations was matched to the next three patients without hallucinations. The patients and comparison subjects were compared in terms of scores on the Beck Depression Inventory, Eysenck Personality Questionnaire, Telephone Interview for Cognitive Status, and a structured questionnaire including demographic characteristics, family history, and medical and psychiatric history. Ophthalmologic data were obtained by chart review. **Results:** Of the 100 patients, 13 experienced visual hallucinations. Four variables were significantly associated with having hallucinations: living alone, lower cognition score, history of stroke, and bilaterally worse visual acuity. Hallucinations were not associated with family or personal history of psychiatric disorder or with personality traits. In 11 (84.6%) of the 13 patients, the hallucinations had begun in association with an acute change in vision. **Conclusion:** These results indicate that visual hallucinations are prevalent among patients with macular degeneration. They appear unrelated to primary psychiatric disorder. The predisposing factors of bilaterally worse vision and living alone support an association with sensory deprivation, while history of stroke and worse cognition support a decreased cortical inhibition theory.

(Am J Psychiatry 1992; 149:1701-1706)

Visual hallucinations are associated with a variety of lesions at all levels of the visual system (1-3). Weinberger and Grant (2) reported visual hallucinations in patients with pituitary tumors pressing on the optic nerves and chiasm, noting that the hallucinations were not limited to the area of visual field loss. Lance (4) reported visual hallucinations in patients with homonymous field defects and noted that the hallucinations were confined to the area of visual field loss in all but one patient. Because the calcarine area of the occipital lobe was infarcted in many of these patients, he concluded that it was not the origin of the hallucinations and suggested that the surrounding visual association cortex was. Kolmel (5) reported that 13% of 120 patients with homonymous hemianopia and occipital lobe damage experienced complex visual hallucinations in the hemianopic field. The subjects

stated that the hallucinations occurred hours to days after the loss of vision and disappeared when the hemianopia resolved. He concluded that the hallucinations were "release phenomena" rather than the result of an irritative lesion.

Fitzgerald (6) reported that 15% of 66 patients developed hallucinations within 1 year of becoming blind. He suggested that they were associated with "maladaptive coping" (6, p. 1534) and depression. Lepore (1) examined 104 patients with visual loss due to lesions from the retina to the occipital lobe. He found a 21% prevalence of complex hallucinations or "spontaneous visual phenomena." The severity of the visual acuity loss correlated with hallucinations, but the presence of bilateral as opposed to unilateral disease, older age, or other central nervous system disease did not. He doubted that these hallucinations were associated with psychiatric disorder but did not screen for this.

The eponymous Charles Bonnet syndrome (7-12) has been used to label persistent complex visual hallucinations that occur in the absence of other psychopathology. This syndrome is often associated with eye disease, and insight is fully or partially retained. Most afflicted individuals who have been described were elderly. Controversy exists about whether brain lesions and/or eye

pathology are necessary to produce this syndrome (7, 9, 13-15).

Many theories to explain hallucinations have been proposed. Jackson (16) proposed that the loss of the inhibiting influence of the cortex releases subcortical activity, producing hallucinations. A related theory (17) is that the reduction of sensory input to specific areas of the brain allows previous perceptions into consciousness as hallucinations. Several lines of data support this hypothesis. A review of sensory deprivation studies (18) indicated that approximately 19% of normal subjects undergoing a variety of sensory deprivation regimens develop visual hallucinations. Interestingly, long periods of isolation were not required; some hallucinations occurred within 48 hours. This theory is also supported by research showing that retinal ganglion cells discharge spontaneously. It has been suggested that decreased sensory stimulation allows these discharges to mimic normal stimuli and are misinterpreted as sensory signals (18).

"Black patch psychosis" (19), a term for delirium associated with patching both eyes after cataract surgery, has been offered as further evidence of the sensory deprivation hypothesis. However, unlike patients with the other conditions discussed, these patients are often delirious, and exogenous factors such as anticholinergic eye drops have not been investigated as causes of delirium.

Other data demonstrate that cortical hyperexcitability or irritability can cause visual hallucinations. Forster (20) found that electrical stimulation of Brodmann areas 17 and 18 of the occipital lobe caused visual sensations, whereas stimulation of area 19 produced complex visual phenomena (figures, people, animals). Penfield and Perrot (21) produced hallucinatory experiences in 7.7% of subjects by stimulating cortical or subcortical structures. The high prevalence of visual hallucinations among people with epilepsy also supports this hypothesis.

As some of the aforementioned studies show, the occipital and temporal lobes are associated with visual hallucinations. Furthermore, hallucinations are frequently present in complex partial seizures, which often originate in the temporal lobe. The more posterior the temporal lobe focus, the more complex the hallucinations (22).

At the neurochemical level the reciprocal roles of the dopaminergic and cholinergic systems may play a part in the induction of visual hallucinations. The treatment of Parkinson's disease with dopamine agonists can produce visual hallucinations and other psychotic phenomena (17, 23-25).

Although visual hallucinations are seen in association with a variety of disorders and occur in normal subjects under special environmental conditions, it is notable that only some people experience them in any one circumstance. Numerous predisposing factors have been postulated. They include psychologic stress (11, 26, 27), suggestibility (28), differences in age or education (29), and cognitive deficits (26, 28, 29). Predisposing personality traits have also been studied (28, 30), and some studies have shown an association between hallucinations

and scores on the neuroticism scale of the Eysenck Personality Questionnaire (28, 31). Barber (32) suggested that a small percentage of people can hallucinate at will.

To further characterize the prevalence and description of complex formed visual hallucinations in patients with visual disorders, we undertook a prevalence and case-control study of individuals with a single ophthalmologic disorder. It was hoped that features predisposing individuals to visual hallucinations could be determined and would suggest theories regarding possible pathophysiology. We chose to study patients with age-related macular degeneration because of reports that they have visual hallucinations (33). Also, age-related macular degeneration is not associated with major systemic changes of the body or brain, as are disorders such as diabetic retinopathy, so it is easier to determine whether the loss of vision is a precipitating factor in the visual hallucinations. Also, the defect in macular degeneration may be measured by visual acuity and disciform scar size. This allowed for a test of the hypothesis that larger lesion size or worse acuity would predispose to the development of hallucinations.

METHOD

One hundred seven consecutive patients who had been diagnosed as having age-related macular degeneration by full-time faculty ophthalmologists at a university retinal vascular center were asked to participate in a study that would involve answering questions regarding their vision. One hundred subjects agreed to participate and gave written informed consent. Once enrolled, each patient was screened for hallucinations by one of two interviewers (S.H., M.C.N.) with the following question: "When people have trouble with their eyes, it frequently affects their vision. It may make it difficult to see things that are there, but sometimes people see things that really are not there or see things that other people don't see. Has this ever happened to you?"

Each subject who responded positively was asked to describe the experience so that illusions, dreams, or vivid thoughts could be excluded by the interviewers. Simple visual experiences such as dots, colors, or flashes of light were not considered to be complex visual hallucinations. Any subject who experienced true complex visual hallucinations underwent a structured interview. Data were collected on age; sex; race; level of education; handedness; living situation; medical history; loss of hearing, taste, or smell; head trauma; delirium; current medicines; family history of neurologic and psychiatric disorders; personal psychiatric history; and substance abuse. All subjects were given the Eysenck Personality Questionnaire (34) and the Beck Depression Inventory (35). The Beck scale was chosen because it has been shown reliable in persons over age 60 (36). The Telephone Interview for Cognitive Status (37), a cognitive screen shown to correlate highly with the Mini-Mental State examination (38) but not depend

on visual or motor capability, was also given. A structured questionnaire was then given to further delineate the phenomenology of the visual hallucinations. A copy of the interview instrument can be obtained from the authors.

The case-control method was chosen to identify predisposing factors for hallucinations because the prevalence of positive cases was unknown and a low prevalence was suspected. After each positive case was identified, the next three hallucination-negative patients were identified as comparison subjects and were given the same battery except for the questionnaire further delineating the phenomenology of the visual hallucinations.

Data regarding the patient's visual diagnosis, visual acuity, disciform scar size, and laser treatment history were abstracted from the chart by one of us, an ophthalmologist (D.F.).

The data were analyzed by using the following statistics: Fisher's exact test, chi-square analysis, analysis of variance, logistic regression, and discriminant analysis. The obtained p values were used to assess the strength of association of the variables with the presence of visual hallucinations rather than to test a formal hypothesis. Therefore, no correction for multiple comparisons was used.

Nonadjusted relative risks were calculated for the variables that distinguished the patients with hallucinations and the comparison subjects. Adjusted relative risks were calculated by logistic regression.

RESULTS

Thirteen of the 100 patients screened positive for visual hallucinations, giving a prevalence of 13%. Thirty-nine hallucination-negative patients served as comparison subjects.

The mean age of the 52 subjects was 74.9 years (SD=7.5); 86.6% were white (N=45), and 42.3% were male (N=22) and 57.7% were female (N=30). The mean education level was 12.5 years (SD=2.5). The mean visual acuity was 20/105 for either eye (SD=78.5).

As shown in table 1, the hallucinators differed significantly from the comparison subjects on the variables of living alone, having a personal history of stroke, having bilateral visual acuity of 20/60 or worse, and score on the Telephone Interview for Cognitive Status. A score of 33 on the Telephone Interview for Cognitive Status was used to divide the groups into those with better and worse cognition. This score was chosen because the distribution of scores was bimodal. The hallucinators were more likely to score 33 or less (table 1).

Several variables showed nearly significant differences between the patients with and without hallucinations (table 1). These variables were hearing loss, female sex, age, and visual acuity in the patient's best eye. This last variable was used as a measure of best acuity.

Logistic regression and discriminant function analysis were used to identify a model of variables that could best predict whether a patient with macular degeneration would or would not have visual hallucinations. A four-factor model (using the four significant variables of living alone, history of stroke, lower score on the Telephone Interview for Cognitive Status, and bilateral vision of 20/60 or worse) determined by logistic regression gave the overall best prediction of 87.8%. It correctly classified 61.5% of the hallucinators and 97.2% of the comparison subjects. Discriminant analysis was performed on the four significant variables as well as the four variables that showed nearly significant differences (hearing loss, female sex, older age, worse visual acuity in the best eye) but resulted in a lower overall predictive value than did the logistic regression. The adjusted and nonadjusted relative risks for the significant variables and the nonadjusted relative risks for the nearly significant variables are shown in table 2.

Also of interest were the variables found not to be significantly different between the hallucinators and comparison subjects. These included level of education, handedness, number of concurrent medical disorders, loss of taste or smell, history of head trauma or delirium, number of medications, drug and alcohol use (past or current), family or personal history of neurologic disorder (Parkinson's disease, stroke, epilepsy, or de-

TABLE 2. Nonadjusted and Adjusted Relative Risks for Visual Hallucinations in 52 Patients With Macular Degeneration

Variable	Nonadjusted Relative Risk		Adjusted Relative Risk ^a	
	Risk	95% Confidence Interval	Risk	95% Confidence Interval
Living alone	4.23	1.10-16.19	2.48	0.47-113.14
History of stroke	11.40	1.07-121.70	15.50	0.89-270.5
Lower score on Telephone Interview for Cognitive Status	11.40	1.35-96.34	13.05	0.97-175.75
Bilateral vision of 20/60 or worse	4.33	1.12-16.78	4.59	0.85-24.91
Hearing loss	3.60	0.94-13.79		
Female sex	3.16	0.75-13.29

Worse vision in best eye	3.32	0.87-12.67		

^aDetermined by logistic regression using a four-variable model (living alone, history of stroke, lower cognition score, bilateral vision of 20/60 or worse).

mentia), and family or personal history of psychiatric disorders (affective disorder, schizophrenia, anxiety, or other). There were no differences between the hallucinators and the comparison subjects in scores on the Beck Depression Inventory or Eysenck Personality Questionnaire. There were no differences in history of laser treatment to eyes or disciform scar size.

Characteristics of the hallucinations are shown in table 3. The patients saw a wide variety of hallucinations; some patients saw only one form, whereas others saw many different forms. They included animals, people, both full bodies and faces, scenery, objects, and geometric shapes. Examples include "elaborate rows of Victorian houses, with pastel colors," "frightening faces with brown hair that would grow to cover the face," "a collie dog," "moving gold chains," "red brick buildings," "groups of brown-red squares," "groups of men wearing elaborate fifteenth-century garb," and "two militarized teams of men playing football."

The period during which the patients had seen these hallucinations ranged from 2 to 36 months at the time of the interview. Eleven subjects (84.6%) reported an acute change in vision coincident with the beginning of the hallucinations, while two (15.4%) described an insidious onset. Three (23.1%) noted that the hallucinations always occurred during the same time of day. Three (23.1%) found they occurred more often in bright light, two (15.4%) said they occurred more often in dim light, and eight (61.5%) found no difference. Four (30.8%) could make the hallucinations temporarily go away by blinking, one (7.7%) could do so by trying to focus on the hallucinations, and eight (61.5%) were unable to affect the hallucinations. No patient could induce a hallucination.

None of the visual hallucinations were accompanied by a hallucination in another sense (auditory, olfactory, tactile, or gustatory). Although all of the subjects believed that the hallucinations were related to their eye

disorder three (23.1%) had occasionally acted on the hallucination (e.g., tried to touch it, push it away). Citing reasons such as fearing "others would think [they were] crazy," three (23.1%) had never told anyone of these experiences before this study. Of the 10 (76.9%) who had told someone, five had told their doctors.

DISCUSSION

The occurrence of complex visual hallucinations in patients with age-related macular degeneration is not uncommon, and a prevalence of 13% was found in this

consecutive group of patients. This is important to know as some patients will not tell anyone, including their doctors, unless asked. Many patients expressed relief at knowing that others had this experience and that doctors were trying to study this phenomenon. The results of this study might reassure patients and teach physicians that having visual hallucinations with age-related macular degeneration is not associated with depression, other primary psychiatric disorder, or abnormal personality.

Given that neurologic diseases such as epilepsy, dementia, and Parkinson's disease are associated with visual hallucinations, it was interesting that these disorders were not found among our hallucinators. Similarly, alcohol and drug use, number of medications, and number of medical disorders were not associated with the hallucinations. This suggests that these variables were not the cause of visual hallucinations in patients who happened to also have age-related macular degeneration. Also, factors suggested by previous studies as associated with hallucinations, such as education, depression, and personality traits (especially score on the Eysenck Personality Questionnaire neuroticism scale), were not supported in this study. No support was found for patients' "hallucinating at will."

The close association noted by the hallucinators between a sudden change in vision (due to laser treatment, hemorrhage, etc.) and the onset of the hallucinations also suggests that the visual hallucinations were related to the visual disorder. Further, the facts that bilateral visual acuity of 20/60 or worse was significantly associated with hallucinations and that the hallucinators had somewhat worse vision in the best eye suggest a relationship between the severity of eye disease and the phenomenon of hallucinations. However, since only 13% of the patients with age-related macular degeneration experienced visual hallucinations and since no risk factor distinguished 100% between the hallucinators and the nonhallucinators, the variables found to be significantly different between the hallucinators and comparison subjects might best be considered predisposing factors.

The theory of sensory deprivation is supported by the findings of bilateral as opposed to unilateral disease and more severe visual impairment among the subjects with hallucinations. Also, half of the hallucinations were limited to the area of visual field loss, i.e., the area of sensory deprivation. Living alone, although less clearly related, might also be linked with less sensory stimulation. The nearly significant association between hearing loss and hallucinations also supports a sensory deprivation model, as one more route of sensory input is reduced.

Two risk factors identified here, lower cognition score and personal history of stroke, support the hypothesis that decreased cortical inhibition allows subcortical or adjacent cortical areas to "release" discharges, causing hallucinations. Our results also support previous studies linking cognitive deficits with hallucinations (26, 28, 29). Furthermore, cognitive deficits in Parkinson's disorder patients have also been associated with

risk of hallucinations (25). A study of patients with Charles Bonnet syndrome (7) revealed that two of six subsequently developed dementia, which raises the question of whether visual hallucinations in patients with age-related macular degeneration may be a risk factor for or, more likely, an early symptom of dementia. A follow-up study of these patients may answer this question. The nearly significant association between older age and hallucinations could also indicate that greater age-related cortical atrophy is a risk factor, but we have no data to support or refute this possibility. The work of Foerster (20), who produced complex visual hallucinations by stimulating the visual association cortex, makes visual association cortex area 19 a possible candidate for the brain region "releasing" visual hallucinations. Interestingly, an abnormally high number of neurofibrillary tangles are found in the visual association cortex of patients with Alzheimer's disease (39), a disease in which 10% of patients have visual hallucinations, with relative sparing of the primary visual cortex (40).

An examination of phenomena in other visual disorders and over a broader age range is now underway. This may help clarify the importance of age as a risk factor, since all our patients were over age 55. It will also help clarify whether this phenomenon is present in visual disorders with different pathologies and further define other factors found in this study to be associated with hallucinations. To clarify whether cortical atrophy or cortical hyperexcitability is a risk factor, it would be helpful to study brain structure (with magnetic resonance imaging and computerized tomography) and function (with EEG, visual evoked potentials, single photon emission computed tomography, and positron emission tomography).

Elderly Israeli Holocaust Survivors During the Persian Gulf War: A Study of Psychological Distress

Zahava Solomon, Ph.D., and Edward Prager, Ph.D.

***Objective:** The aim of the current study was to systematically assess the psychological effects of the Persian Gulf War on a nonclinical group of elderly Israeli civilians with and without a Holocaust background. **Method:** Sixty-one elderly Holocaust survivors and 131 elderly civilians without a Holocaust background completed questionnaires in their homes. Measures included sense of safety, symptoms of psychological distress, and levels of state and trait anxiety. **Results:** Findings indicate that Holocaust survivors perceived higher levels of danger and reported more symptoms of acute distress than comparison subjects. In addition, they displayed higher levels of both state and trait anxiety. **Conclusions:** Findings do not support the notion that prior experience with extreme stress has an inoculating effect that leads to greater resilience in dealing with other forms of stress. On the contrary, Holocaust experience was found to render the elderly more vulnerable rather than less. These findings of greater vulnerability among Holocaust survivors are of particular significance since they stem from a nonclinical group.*

(Am J Psychiatry 1992; 149:1707-1710)

Over a period of 6 weeks, from mid-January to the end of February 1991, the residents of Israel were exposed to a war in which 39 Iraqi Scud missiles, not aimed at military targets, fell in the heart of civilian residential areas. The citizens of Israel were required to equip themselves with masking tape, plastic sheeting, wet towels, and baking soda and were issued gas masks to protect themselves against the Iraqi threat to use biological and chemical weapons. Life in Israel carried on in what became known as the "emergency routine," that is, an ongoing series of emergency alerts separated by hours or days of relative calm. Some places, primarily those providing vital services, remained open in the mornings, but social and cultural activities were almost completely curtailed so as to avoid large gatherings. In the late afternoon, most people retired to their homes, close to their sealed rooms and gas masks, and nervously readied themselves for nighttime, when the missiles would fall.

Despite the fact that millions of people around the globe have been exposed in this century to the horrors of war, and although there have been many studies of war-induced stress, relatively few have focused on civil-

ians. There are a few pioneering works (1, 2), but these have primarily been either impressionistic or based on small samples. Research on high-risk segments of the population are particularly lacking. The present study examined the responses of one group that was identified during the war as being at high risk for psychological distress: the elderly.

Approximately 10% of the population of Israel is over age 60, and in the greater Tel Aviv area (the area that sustained the most missile attacks during the war), the elderly constitute around 14% of the population. While many younger people left the city during the war in search of safer areas, most of the elderly remained at home. Certain aspects of the war were especially distressing for the elderly: community support activities were drastically curtailed during the war and senior citizens' centers were closed, since people refrained from leaving home when not absolutely necessary. Protective devices such as gas masks, which require a certain amount of manual dexterity, also posed problems for many of the elderly. For those with impaired vision or hearing, seclusion in the sealed room often aggravated their sense of isolation from the outer world. Fear of not hearing the warning sirens or difficulty in understanding the emergency instructions broadcast over the media distressed and worried many. These difficulties were especially severe among those who lived alone; their loneliness was exacerbated during the war.

While the war was stressful for all the elderly in Israel, there was one group in particular whose prior life experiences might be expected to affect their responses

to the current crisis: Holocaust survivors. Many of this group who immigrated to Israel after World War II seemed, at least outwardly, to have overcome the horrors of their past. Most have raised families and have led productive and full lives. Some of them, however, are haunted by the past and remain scarred by posttraumatic stress (3). The literature is divided with regard to the extent and depth of long-range impairment resulting from the Holocaust. On the one hand, some claim that the Holocaust left a permanent mark and that a large percentage of survivors suffer from severe and debilitating disorders such as chronic anxiety and depression (4) or personality constriction (5). On the other hand, others believe that severe disorders are to be found only among a minority and that most survivors do not manifest serious psychological impairment. On the contrary, most of them lead productive lives despite their ordeal (6).

There is, however, consistent evidence that people who undergo extreme stress are left more vulnerable and more sensitive to *future* adversity (7). Moreover, even people who have seemingly overcome their traumatic experiences may suffer from heightened vulnerability in the future (8) and in extreme cases from reactivation of acute stress responses following exposure to stimuli that symbolize or recall the original traumatic experience (9). The work of Christenson and colleagues (10) is especially relevant in this regard. They examined reactivation of posttraumatic reactions among the elderly. In their work they found that life events such as retirement, children leaving home, death of a loved one, and other stressful events served as triggers that accelerated and unmasked latent posttraumatic stress disorder (PTSD) among American World War II combat veterans.

Clinical impressions indicate that while the Persian Gulf War was stressful for all the population of Israel, it was an especially painful reminder for the Holocaust survivors. The feeling of being "sitting ducks," the sense of impending doom, the threat to use gas (purchased in Germany), and the rows of decontamination showers positioned at the entrance to every hospital (which reminded the survivors of the entrance to the gas chambers in the concentration camps) all made the war particularly stressful for the Holocaust survivors.

The aim of the current study was to systematically assess the psychological effects of the Persian Gulf War on elderly civilians with and without a Holocaust background. Specifically, we examined sense of safety, symptoms of psychological distress, and levels of state and trait anxiety.

METHOD

Subjects

A total of 192 subjects participated in this study. Sixty-one (31.8%) were Holocaust survivors and 131 (68.2%) did not have this background. In the Holocaust group, the mean age was 68.3 (SD=7.2) and 33.3%

(N=20) were men. In the non-Holocaust group, the mean age was 72.9 (SD=7.5) and 38.5% (N=50) were men. Thirty-six percent of the subjects lived in kibbutzim (communal settlements), and the remaining 64% resided in cities in the center of Israel. Five percent of the subjects were born in Israel, and the remainder were of European origin. Seventeen percent of the respondents had completed elementary school, 53% had finished high school, and 30% had studied beyond high school. Fifty-seven percent were married at the time of the study, 37% were widowed, 2% were divorced, and 4% had never married. Sixty-six percent of the respondents described themselves as secular, 26% as traditional, and 8% as orthodox. Twelve percent were residents of an urban community home for the aged; the remainder lived in their own homes, whether in kibbutzim or in cities.

Procedure

In each community, a local social worker who was well acquainted with the elderly residents of the area and experienced in working with this population was recruited to administer questionnaires. The social worker approached potential subjects and requested their consent to participate in the study. Subjects completed the questionnaires in the presence of the social workers, who answered questions as necessary.

Subjects were first presented with a brief questionnaire inquiring about sociodemographic variables such as age, sex, education, religious observance, marital status, place of residence, country of origin, and current health status. Subjects were then queried in detail about prior traumatic experiences, such as internment in concentration camps during World War II, participation in wars, loss of loved ones, and personal life events. Subjects were also asked to note if they had experienced any event similar to the Persian Gulf War in the past.

Sense of safety. Subjects were asked to rate their level of personal safety during the war in a number of different areas on a scale ranging from 1 (not at all) to 5 (very much). Internal validity of the nine-item questionnaire was examined through factor analysis with varimax rotation. This analysis yielded three principal factors (eigenvalue greater than 1) that explained 62.6% of the variance.

In the current study, we employed only the first factor, which explained 31.0% of the variance and related to the subjects' perceptions of danger. This factor includes questions such as "To what degree do you feel that your life is in danger?" "To what degree do you assess that the country of Israel is in danger of being annihilated?" and "To what degree do you think that your family is in danger?"

State-Trait Anxiety Inventory. This questionnaire (11) is a standardized measure of anxiety that has been used frequently in studies of traumatic stress throughout the world, particularly with civilian populations, thus allowing for comparisons with other samples (2). It is composed of two 20-item scales. The State Anxiety

scale assesses the person's *current* or transitory emotional state, and the Trait Anxiety scale examines the way the subject *generally* feels.

Psychological Distress in Wartime. This self-report measure, devised for the current study, comprises 19 items all of which examine typical responses to extreme stress. Unfortunately, no standardized criteria for assessment of acute stress reactions are currently available, and even the most recent diagnostic and statistic manual, *DSM-III-R*, does not include a relevant category. The closest and most relevant nosological category in *DSM-III-R* is that of PTSD. The symptoms required for diagnosis of PTSD (e.g., distancing from others, nightmares, startle response, hypervigilance) were, therefore, chosen as the basis for most of the items in this questionnaire. Since this assessment was conducted *during* rather than after the exposure to the stressor, however, not all of the *DSM* criteria were appropriate, and, of course, the criterion of 1-month duration could not be met. For this reason, no attempt was made to address the issue of diagnosis. Subjects were asked to rate the presence of each symptom in the past week on a 4-point scale ranging from 1 (not at all) to 4 (very often). The mean score on this scale was 36.4 ($SD=11.7$). In order to examine internal consistency, Cronbach's alpha was calculated and was found to be high (0.90).

RESULTS

In order to examine differences between subjects with and without a Holocaust background, a multivariate analysis of the four dependent variables was conducted. The analysis indicated a large and significant effect ($F=8.14$, $df=4$, 109, $p<0.001$). All four dependent variables were significantly different between the two groups (all p values were <0.001); elderly Holocaust survivors perceived significantly higher levels of danger, experienced more emotional distress, and had higher levels of both state and trait anxiety than subjects without a Holocaust background.

In order to examine whether there were differences in background variables between the two groups, a multivariate analysis of variance (MANOVA) was performed with the sociodemographic characteristics (age, sex, education, religiosity, health status, and proximity to bomb sites) as independent variables and Holocaust background as the dependent variable. This analysis yielded a significant main effect ($F=10.19$, $df=6$, 173, $p<0.001$) because of the fact that the Holocaust survivors were significantly younger ($F=21.51$, $df=1$, 179, $p<0.001$), less educated ($F=14.37$, $df=1$, 179, $p<0.001$), and more religious than the other subjects ($F=12.88$, $df=1$, 179, $p<0.001$) and were closer to the bomb sites ($F=16.00$, $df=1$, 179, $p<0.001$). It was therefore decided to perform the MANOVA on the dependent variable with the background variables as covariates. Table 1 presents the means and standard deviations of the four dependent variables separately for

TABLE 1. Psychological Ratings During the Persian Gulf War for Elderly Israeli Survivors of the Holocaust and Other Elderly Subjects^a

Measure	Holocaust Survivors (N=61)		Other Subjects (N=131)		F (df=1, 100)
	Mean	SD	Mean	SD	
Perceptions of danger	-0.2	0.9	0.5	1.1	2.29
Psychological distress	42.9	11.9	33.0	10.1	6.20
State anxiety	47.4	13.2	36.5	13.0	6.27
Trait anxiety	50.3	10.4	41.5	7.4	7.53 ^b

^aA multivariate analysis of covariance was performed with age, sex, education, religiosity, health, and proximity to bomb sites as covariates. Overall $F=2.43$, $df=4$, 97, $p<0.05$.

^b $p<0.05$, with Bonferroni correction (12) for multiple comparisons.

Holocaust survivors and the other respondents and the results of the multivariate analysis, covarying for the background variables.

As can be seen in table 1, the effect of the Holocaust was marginally significant ($p<0.05$) after the effects of the background variables were removed. When the structure of the relationships was examined with univariate analyses, we found that perception of danger was not significantly different between the two groups. In univariate analyses of variance we found that state anxiety and psychological distress were different between the two groups ($p<0.05$). These significance tests should be interpreted cautiously because multiple comparisons were performed. We therefore performed a more conservative estimate of the significance level, using the Bonferroni correction (12), and found that the two groups did not differ significantly. Trait anxiety was significantly different between the two groups after the background variables were covaried ($p<0.05$, with Bonferroni correction).

In sum, results show that even after a wide range of background variables were controlled, there were still marginally significant differences between the Holocaust survivors and the other elderly civilians, with the Holocaust survivors experiencing more difficulties than the other subjects.

DISCUSSION

The findings of this study indicate that elderly survivors of the Holocaust suffered considerable emotional distress during the Persian Gulf War. It should be noted that differences between the Holocaust survivors and the other elderly subjects were evident even when a most conservative analysis of the data was conducted that controlled for a wide range of background variables, some of which may themselves have been a function of Holocaust experiences (e.g., health status).

These findings do not support the notion that prior experience with extreme stress has an inoculating effect that leads to greater resilience in dealing with other forms of stress. Norris and Murrell (13), for example,

studied a large sample of elderly flood victims and found evidence for both direct tolerance (exposure to a particular stressor reduces the subsequent impact of the *same* stressor) and cross-tolerance (exposure to one type of stressor lowers the pathogenicity of a *different* stressor). In the current study, however, there were no such effects. On the contrary, Holocaust experience was found to render the elderly *more* vulnerable rather than less. In fact, using a cutoff point of 44 on the Trait Anxiety scale, as suggested by Himmelfarb and Murrell (14), we found that a large proportion of the Holocaust survivors (51%) were at risk for a "degree of psychological distress that would require intervention" (14, p. 162). Moreover, the proportion of Holocaust survivors with Trait Anxiety scale scores above the cutoff point was more than *double* that of the other subjects (24%).

These findings are consistent with those of prior studies that have demonstrated greater vulnerability to stress among trauma victims. Prior studies by this group (9), for example, have found that the greater the similarity between two traumatic events, the greater the chance for a reactivation of the original stress response after the second event. It should be kept in mind, however, that even a very different stressor may lead to reactivation of an earlier stress response among the elderly (10).

There is some controversy in the literature with regard to the long-term effects of the Holocaust on survivors. Titchener (15, 16) has suggested that a process of posttraumatic decline may take place in the years after exposure to a traumatic event and that permanent characterological effects of the trauma may be observed, particularly in terms of proneness to anxiety reactions. Niederland (4) has characterized the "survivor syndrome" as a chronic state of anxious bland depression. One major limitation of most reports on Holocaust survivors has been that formulations of the survivor's adjustment during and after internment have been based primarily on analysis of individuals who were seeking help for emotional problems. Few studies have used normal samples. Researchers such as Leon and colleagues (6) have claimed that generalizations about survivors as a group were based on the analysis of clinical cases and have questioned the generality of these findings. In fact, community studies have often failed to uncover significant pathology among Holocaust survivors.

The current findings of both acute stress and higher levels of state (acute) and trait (characterological) anxiety are, therefore, of significance, since we used a normal group as well as a comparison group of the same ethnic and cultural background as the survivors.

Utilization of Neuropsychiatric Diagnostic Tests for General Hospital Patients With Mental Disorders

Mark Olfson, M.D.

Objective: The author's goal was to determine the frequency and distribution of neuropsychiatric diagnostic tests provided to general hospital patients with mental disorders. **Method:** Data from the 1989 National Hospital Discharge Survey were analyzed to determine the number, proportion, and general characteristics of 11,628 discharged patients with primary diagnoses of mental disorders who underwent computerized tomography (CT) scanning of the head, EEG, and magnetic resonance imaging (MRI) of the brain. **Results:** Of the discharged patients with mental disorders, 5.1% had received CT scans, 2.8% had received EEGs, and 0.7% had received MRI. These rates were below the rates for patients discharged with primary diagnoses of neurological disorders but above the rates for patients discharged with primary diagnoses of other medical disorders. Among the patients discharged with mental disorder diagnoses, the likelihood of receiving a CT scan or an EEG was greater if the primary diagnosis was an organic disorder or if the secondary diagnosis was a medical disorder. Patients over age 65 were also more likely to have received a CT scan. Hospital size and location had a modest influence on the likelihood of receiving a CT scan or EEG, but the ownership of the hospital and the patient's source of payment were not significant influences. **Conclusions:** Neuropsychiatric diagnostic testing is selectively utilized in the routine treatment of general hospital psychiatric inpatients. Clinical variables rather than institutional or financial variables appear to be the most powerful predictors of which patients are selected to receive these tests.

(Am J Psychiatry 1992; 149:1711-1717)

General hospitals have assumed a leading role in acute inpatient psychiatric care (1). According to recent national estimates, general hospitals account for more than half of all psychiatric inpatient admissions (2). In relation to this large commitment of resources, surprisingly little is known about the composition of routine care. This article focuses on one aspect of psychiatric practice in general hospitals: the utilization of neuropsychiatric diagnostic procedures.

Patient assessment remains a major task in psychiatric hospitalization (3, 4). Because psychiatric symptoms are often early manifestations of remediable central nervous system (CNS) disease, psychiatric assessment commonly includes an effort to uncover brain pathology (5, 6). Anatomic and functional brain imaging technologies play an important role in this process. EEG, computed tomography (CT), and magnetic resonance

imaging (MRI) are three procedures capable of providing information that dramatically focuses clinical management on underlying CNS disease (7-9).

Enthusiasm for technologically sophisticated diagnostic procedures has been tempered by concerns about rising medical costs. Fiscal control of technology has been targeted as an important means of slowing the ever-increasing cost of health care (10). Concerns about rising health care costs have led researchers to examine the clinical yield of various diagnostic procedures. In the case of CT scans of the head and EEGs, research with psychiatric inpatients suggests that indiscriminate testing has limited clinical utility and may be an inefficient use of precious medical resources (11-13). In the absence of clear clinical indications, CT scanning and EEG rarely lead to the detection of previously unknown organic disease or changes in patient treatment. Clinical research further suggests that MRI of the brain should be ordered only when there is strong suspicion of gross neuropathology (14).

The rate and pattern of neuropsychiatric diagnostic testing for hospitalized patients with mental disorders have received scant attention. Previous research in this area has been limited to utilization reviews at individual hospitals. These hospitals are typically large urban uni-

Received Oct. 16, 1991; revision received Feb. 12, 1992; accepted March 6, 1992. From the Department of Psychiatry, Cornell University Medical College. Address reprint requests to Dr. Olfson, New York State Psychiatric Institute, Box 47, 722 West 168th St., New York, NY 10032.

versity facilities. Because clinical practice at these facilities may not be representative of general patterns of care, this research may not accurately portray broader trends in practice. A more accurate assessment of inpatient practice requires a nationally representative sample of inpatient test utilization.

Previous research suggests that the rate of neuropsychiatric test utilization varies by treatment setting. Depending upon the setting, rates of CT head scanning for psychiatric inpatients have been reported to range from 3% to 100% (8, 11, 15, 16) and rates of EEG to vary from 18% to 33% (13, 17). At present, there is little information on the utilization of MRI technology for inpatients with mental disorders.

This study is the first exploration of the utilization of CT head scanning, EEG, and MRI of the brain for a nationally representative sample of general hospital inpatients with mental disorders. The results suggest that neuropsychiatric diagnostic procedures are provided to only a small proportion of general hospital inpatients with mental disorders and that clinical variables rather than institutional or financial variables are of greatest importance in determining test utilization.

METHOD

The data for this report were drawn from the 1989 National Hospital Discharge Survey (18), a nationwide survey of inpatient utilization conducted by the National Center for Health Statistics. The survey selects a national probability sample of patients discharged from non-federal-government hospitals whose average length of stay is less than 30 days. Because over 95% of these facilities are general hospitals, they are referred to as such in this report.

The National Hospital Discharge Survey is conducted by means of a three-stage sampling design. The first stage involves selecting a probability sample of primary sampling units. The second stage involves selecting all hospitals within the chosen primary sampling units that have 1,000 or more beds or 40,000 or more annual discharges and selecting a probability sample of smaller hospitals. The third stage involves selecting discharges from the chosen hospitals by a systematic random-sampling technique. This strategy oversamples frequent users of inpatient care, but it accurately reflects overall provision of inpatient care in short-stay hospitals other than those run by the federal government.

The National Hospital Discharge Survey consists of data abstracted from the face sheets of patients' medical records. The abstracted data include demographic information, discharge status, length of hospital stay, discharge diagnoses, and inpatient procedures. Discharge diagnoses and procedures are reported according to the ICD classification system.

The survey also provides information on hospital size, geographic location, and ownership. Geographic location is reported for the four regions of the United States used by the U.S. Bureau of the Census. Owner-

ship of hospitals is reported in three broad categories: proprietary, not-for-profit, and government. Because general hospitals operated by the federal government are outside the scope of the National Hospital Discharge Survey, surveyed government facilities are limited to hospitals operated by state or local governments.

Discharges are divided into those for which the primary discharge diagnosis was a mental disorder (ICD-9-CM codes 290-319), those for which the primary discharge diagnosis was a neurological disorder (ICD-9-CM codes 320-359), and those for which the primary discharge diagnosis was a medical disorder (ICD-9-CM codes 001-289, 360-999, and V01-V82). Most of the analyses concern discharges with primary mental disorder diagnoses.

This report focuses on the utilization of three diagnostic procedures: CT scan of the head (ICD-9-CM procedures code 97.03), EEG (code 89.14), and MRI of the brain (code 88.91). Some analyses involve aggregating patients with mental disorders into six groups on the basis of their primary discharge diagnoses. These groups include organic disorders (codes 290, 293, 294, 310), schizophrenic disorders (code 295), affective disorders (codes 296, 311, 298.0), drug- and alcohol-related disorders (codes 291, 292, 303-305), neurotic disorders (code 300), and other disorders (codes 297, 298.1-299, 301, 302, 306-309, 312-319). These diagnostic groupings are a modification of those developed by the National Institute of Mental Health (19).

A weighting system has been developed by the National Center for Health Statistics to produce national estimates from National Hospital Discharge Survey sample estimates (18). The construction of the patient weights is based on inflation by the reciprocal of sampling probability. The percentages provided in this report are based on weighted estimates.

Logistic regressions were used to estimate the likelihood (relative risk) that patients discharged with primary diagnoses of mental disorders would have received a CT scan of the head or an EEG during their hospital stay. Results are presented as odds ratios with associated 95% confidence intervals. These computations were made with unweighted data.

Because the sample survey contained a relatively small number of discharged patients with primary mental disorder diagnoses who received an MRI of the brain (N=62), only limited analyses of these discharges are presented.

RESULTS

Frequency of Diagnostic Testing

Table 1 presents the frequency of CT scans of the head, EEGs, and MRI of the brain for general hospital inpatients with primary diagnoses of mental disorders, neurological disorders, and medical disorders. Of the estimated 1.51 million patients discharged from U.S. general hospitals in 1989 with primary diagnoses of mental disorders, ap-

TABLE 1. Frequency of Selected Diagnostic Procedures Provided to Inpatients Discharged From General Hospitals With Three Groups of Primary Diagnoses^a

Procedure	Patients With Mental Disorders			Patients With Neurological Disorders			Patients With Medical Disorders		
	National Estimate (1,514,200)	%	Study Sample (N=11,628)	National Estimate (431,700)	%	Study Sample (N=3,030)	National Estimate (32,885,300)	%	Study Sample (N=218,835)
CT scan of the head	77,900	5.1	624	62,900	14.6	508	686,500	2.1	5,865
EEG	42,700	2.8	346	34,400	8.0	268	161,800	0.5	1,307
MRI of the brain	10,000	0.7	62	16,400	3.8	129	72,300	0.3	654

^aData are from the 1989 National Hospital Discharge Survey (18). Federal government hospitals are not included. Mental disorders are defined as ICD-9-CM codes 290–319, neurological disorders as codes 320–359, and medical disorders as all other ICD-9-CM codes. Percentages are based on weighted sampling.

proximately 78,000 (5.1%) had received CT scans of the head, 43,000 (2.8%) had received EEGs, and 10,000 (0.7%) had received MRI of the brain.

Patients with mental disorders tended to undergo neuropsychiatric procedures less frequently than patients with neurological disorders but more frequently than patients with other medical disorders. Patients with mental disorders were less than half as likely as patients with neurological disorders to receive either a CT scan or an EEG and less than one-fifth as likely to receive MRI. At the same time, patients with mental disorders were more than twice as likely as patients with other medical disorders to receive a CT head scan or MRI and more than five times as likely to receive an EEG (table 1).

The vast majority (93.2%) of patients discharged from general hospitals with diagnoses of mental disorders did not undergo any of the three neuropsychiatric procedures. Overall, patients with mental disorders accounted for only a modest proportion of the neuropsychiatric tests ordered for patients discharged from general hospitals (17.9% of the EEGs, 10.1% of MRI of the brain, and 9.4% of the CT head scans).

Patients with mental disorders who received any one of the diagnostic tests were likely to receive others. More than one-quarter (30.4%) of the patients with mental disorders who had a CT scan of the head also had either an EEG or MRI of the brain. More than one-third (44.4%) of the patients with mental disorders who underwent MRI also had either a CT scan or an EEG. Over one-half (60.3%) of the patients with mental disorders who received an EEG also received either a CT scan or MRI.

Demographic Characteristics and Sources of Payment

Selected demographic characteristics of the patients with mental disorders who received CT scans of the head or EEGs are presented in table 2. Patients who received CT scans of the head tended to be older than patients who received EEGs, and patients who received EEGs tended to be older than those who did not undergo either procedure. Over one-third (40.6%) of the patients with mental disorders who received CT scans of the head and nearly one-quarter (23.2%) of those who received EEGs were over 65 years of age.

Other	65	11.8	36	15.0	961	10.0

^aData are from the 1989 National Hospital Discharge Survey (18). Percentages are based on weighted sampling.

^bFor patients who had CT scans of the head, mean=52.8 years (SD=22.8); for patients who had EEGs, mean=43.9 years (SD=22.1); for patients who had neither procedure, mean=39.1 years (SD=17.9).

For patients with mental disorders, the most common primary source of payment for hospitalization was private insurance (36.7%). Medicare (23.9%) and Medicaid (19.2%) were also common sources of payment. Self-pay (10.5%) and other sources (9.7%) were less common.

CT scans of the head were provided to 9.9% of Medicare patients with mental disorders, 5.1% of self-paying patients, 3.8% of Medicaid patients, and 3.3% of privately insured patients. EEGs were provided to 4.1% of self-paying patients with mental disorders, 3.6% of Medicare patients, 3.0% of Medicaid patients, and 2.3% of privately insured patients.

Discharge Status

A majority of the general hospital inpatients with mental disorders (79.1%) received routine discharges. A

TABLE 3. Frequency of CT Scans of the Head and EEGs Provided to Inpatients Discharged From General Hospitals With Primary Diagnoses of Selected Groups of Mental Disorders^a

Procedure	Organic Disorders (N=613)		Schizophrenic Disorders (N=1,690)		Affective Disorders (N=2,996)		Drug- and Alcohol-Related Disorders (N=3,792)		Neurotic Disorders (N=707)		Other Disorders (N=1,830)

^aData are from the 1989 National Hospital Discharge Survey (18). Percentages are based on weighted sampling.

smaller proportion were discharged against medical advice (7.0%), were transferred to other institutions (13.7%), or died while they were in the hospital (0.2%).

Patients with mental disorders who had CT scans of the head or EEGs were transferred to other institutions at higher rates (17.3% and 18.8%, respectively) than patients with mental disorders who did not have either of these tests (13.4%). As compared with the transferred patients who did not undergo either procedure, those who had CT scans and those who had EEGs were more often sent to long-term care facilities (55.8%, 76.1%, and 67.1%, respectively). The remainder of the transferred patients with mental disorders were sent to other short-term hospitals.

The length of stay of patients with mental disorders who received CT scans of the head (mean=16.6 days, SD=26.6) and EEGs (mean=17.3 days, SD=28.8) was several days longer than that of patients with mental disorders who did not receive either test (mean=12.9 days, SD=15.4).

Discharge Diagnoses

The percentages of discharged patients with primary mental disorders in the six broad diagnostic groupings were as follows: drug- and alcohol-related disorders, 29.9%; affective disorders, 26.8%; schizophrenic disorders, 13.5%; neurotic disorders, 7.4%; organic disorders, 6.0%; and other disorders, 16.4%. Of the various groups, patients with organic disorders were the most likely to receive CT scans of the head and EEGs (table 3). The largest subgroup of patients with organic disorders (N=259) consisted of patients diagnosed as having senile and presenile organic psychotic conditions (ICD-9-CM code 290). Nearly one-quarter (23.7%) of the patients with senile or presenile organic psychotic conditions received CT scans of the head, and 10.1% received EEGs.

The number of listed discharge diagnoses was greater for patients who had received CT head scans (mean=3.91, SD=1.80) and EEGs (mean=3.64, SD=1.74) than for patients who did not undergo either procedure (mean=2.83, SD=1.65). Over two-thirds of the patients with mental disorders who received CT scans of the head or EEGs were given three or more discharge diagnoses (78.3% and 67.3%, respectively). In contrast,

only about half (49.0%) of those with mental disorders who did not undergo either procedure were given three or more discharge diagnoses.

Secondary medical diagnoses were given to only a small proportion of the patients with mental disorders (6.8%). CT scans were provided to 11.9% and EEGs to 4.8% of the patients with primary mental disorders who received secondary medical diagnoses.

Convulsions (ICD-9-CM code 780.3) and syncope (code 780.2) were the two most common secondary medical conditions of the patients with primary diagnoses of mental disorders. A high proportion of patients with these secondary medical conditions received CT scans of the head (19.2% and 39.0%, respectively) or EEGs (12.2% and 10.7%, respectively).

Hospital Characteristics

As shown in figure 1, the proportions of patients who received CT scans of the head and EEGs tended to increase with increasing hospital size. Patients with mental disorders admitted to general hospitals with 500 or more beds were more than twice as likely as patients admitted to hospitals with fewer than 200 beds to receive CT scans of the head or EEGs.

The majority of patients with mental disorders were admitted to hospitals operated by churches or other not-for-profit organizations (78.0%), rather than hospitals operated by state or local governments (14.2%) or hospitals operated on a for-profit basis (7.8%).

CT scans of the head were provided to a higher proportion of patients in government hospitals (7.6%) than patients in proprietary hospitals (6.2%) or not-for-profit hospitals (4.6%). A similar trend was observed for the frequency with which the patients with mental disorders were provided EEGs (government hospitals, 4.1%; proprietary hospitals, 3.2%; not-for-profit hospitals, 2.5%).

The proportions of patients who received CT head scans and EEGs were analyzed according to geographic region. Patients with mental disorders discharged from hospitals in the west (CT, 6.6%; EEG, 3.8%) and northeast (CT, 5.0%; EEG, 3.4%) had higher rates of testing than patients discharged from hospitals in the midwest (CT, 3.9%; EEG, 2.0%) and south (CT, 3.5%; EEG, 2.4%).

FIGURE 1. Frequency of CT Scans of the Head and EEGs Provided to Inpatients Discharged From General Hospitals With Primary Diagnoses of Mental Disorders, by Hospital Size

Relation of CT Scans of the Head and EEGs to Clinical and Institutional Variables

A logistic regression was conducted to estimate the strength of the association between the clinical and institutional variables and the provision of a CT scan of the head to patients with mental disorders. As shown in table 4, the estimated likelihood (relative risk) of receiving a CT scan of the head was substantially greater for those with a primary discharge diagnosis of an organic disorder, those with a secondary discharge diagnosis of a medical disorder, and those over the age of 65. Hospital location and hospital size had only a modest influence on the estimated likelihood of receiving a CT scan of the head.

A logistic regression was also conducted to estimate the strength of the association between the clinical and institutional variables and the provision of EEGs to patients with mental disorders. The estimated likelihood of receiving an EEG was significantly greater for patients with a primary discharge diagnosis of an organic disorder, those with a secondary diagnosis of a medical disorder, those who were in a hospital with 500 or more beds, and those treated in a hospital in the northeast or west (table 4).

DISCUSSION

The main finding to emerge from this study is that neuropsychiatric diagnostic testing is selectively utilized in the routine inpatient treatment of general hospital patients with mental disorders. The overwhelming majority of general hospital psychiatric inpatients do not receive a CT scan of the head, an EEG, or MRI of the brain.

Approximately one of every 20 (5.1%) of the patients discharged from U.S. general hospitals with a psychiat-

TABLE 4. Clinical and Institutional Factors Associated With the Provision of CT Scans of the Head and EEGs to Inpatients Discharged From General Hospitals With Primary Diagnoses of Mental Disorders^a

Variable	Odds Ratio	95% Confidence Interval
CT scans		
Primary diagnosis of organic disorder (present)	3.01	2.36-3.84
Secondary medical diagnosis (present)	2.71	2.26-3.25
Age of patient (over 65 years)	2.27	1.69-3.06
Geographic region (northeast and west)	1.57	1.32-1.86
Hospital size (500 or more beds)	1.48	1.18-1.86
Hospital ownership (government)	1.19	0.84-1.68
Source of payment (Medicare)	1.03	0.78-1.35
EEGs		
Primary diagnosis of organic disorder (present)	2.74	1.92-3.91

Source of payment (self-pay)	1.08	0.77-1.52
Age of patient (over 65 years)	0.98	0.71-1.36
Hospital ownership (government)	0.80	0.58-1.10

^aData are from the 1989 National Hospital Discharge Survey (18). Groups with higher likelihood of diagnostic procedures are given in parentheses.

ric diagnosis receives a CT scan of the head during the inpatient stay. This figure is in the range previously reported for psychiatric inpatients at a community mental health center (5.6%) (20) and a Veterans Administration medical center (3.6%) (8), but it is substantially lower than rates reported from a private psychiatric hospital (10%) (21) and a general hospital psychiatric consultation service (19%) (15). The estimated national rate of EEGs provided to general hospital inpatients with mental disorders (2.8%) is substantially lower than the rates previously reported from two university-affiliated general hospitals (18% and 33%) (13, 17).

Psychiatric patients who undergo neuropsychiatric diagnostic procedures have relatively complex health care needs. In comparison with patients who do not receive CT scans or EEGs, these patients tend to require longer hospitalization, suffer more commonly from comorbid medical conditions, and are more likely to be transferred to a long-term health care facility.

General hospital psychiatric patients who receive CT scans or EEGs also tend to be older than other psychiatric inpatients, and a larger proportion suffer from organic disorders. The disproportionate use of neuropsychiatric testing for older patients and those with organic disorders or comorbid medical conditions is in accord with published clinical testing guidelines (5, 13, 14). Future studies should examine the specific clinical determinants of ordering neuropsychiatric diagnostic tests for patients with organic disorders and other high-risk groups.

Beyond the finding of more testing for patients with organic disorders, the frequency of testing did not substantially vary by diagnostic group. The frequency of CT head scans for patients with schizophrenia or major affective disorders, for example, was not substantially

different from the frequency for patients with neurotic disorders. This is surprising in light of the clinical indications for CT head scanning, which include a subgroup of psychoses and affective disorders (5), and raises the possibility that CT scans may, in fact, have been underutilized for patients in these subgroups.

Patients with psychiatric diagnoses who are discharged from large hospitals are somewhat more likely than those discharged from small hospitals to have received CT scans or EEGs. Smaller general hospitals, particularly hospitals with fewer than 200 beds, may not generate sufficient clinical demand to offset the high costs of maintaining testing facilities. For hospitals without CT scanning or EEG facilities, the financial costs and clinical risks of transporting patients to hospitals with such facilities may deter test utilization.

Previous research has demonstrated that the composition of psychiatric care varies by hospital type and by the patient's source of payment. Wolff et al. (22) reported that schizophrenic patients admitted to public mental hospitals are less likely to receive a range of psychosocial treatments than schizophrenic patients admitted to private for-profit or private nonprofit psychiatric hospitals. These researchers also found that within private nonprofit psychiatric hospitals, patients with private insurance are more likely to receive some psychosocial treatments than patients without private insurance (22).

In the current study, which was limited to general hospitals, hospital ownership and the patient's source of payment did not have a significant effect on clinical practice. Once psychiatric patients have entered a general hospital, their source of payment and the hospital's type of ownership does not appear to influence the likelihood that a neurodiagnostic workup will be performed. However, the scope of this study may simply have been too narrow to detect the effects of these variables on neuropsychiatric test-ordering practices. A survey that encompasses patients in a broader range of facilities, such as private psychiatric hospitals and state mental hospitals, might have a greater chance of uncovering associations between frequency of test ordering and financial or institutional variables.

There appears to be a modest degree of regional variation in the utilization of neurodiagnostic tests for psychiatric inpatients. General hospitals in the northeast and the west exhibit higher rates of CT head scans and EEGs than hospitals in the south and midwest. The factors that cause this variation are unknown but possibly include lack of agreement about the clinical indications for testing, regional variation in the extent to which physicians base decisions on cost factors, variation in the risk or perceived risk of malpractice, variation in patients' perceptions of quality care, and variation in the extent to which testing serves to reassure patients. An understanding of the sources of regional variation in test utilization may help to promote more cost-effective care.

This study was constrained by limitations in the survey data. Perhaps most importantly, the survey does

not provide information on test results or the clinical consequences of test results. For this reason, the findings do not permit assessment of the complex relation between testing practices and patient outcome. A second limitation concerns the lack of data on admitting diagnoses. Without this information, it is not possible to enumerate patients who are admitted with psychiatric symptoms but who are discovered, during the course of hospitalization, to suffer primarily from medical disorders. Because neuropsychiatric diagnostic procedures may be relatively highly utilized for these patients, the current findings may underestimate the utilization of these procedures for patients admitted to general hospitals with psychiatric complaints.

A third limitation concerns the lack of information about the specialties of the physicians who ordered the tests. Although a majority of general hospital inpatients with primary diagnoses of mental disorders are treated in psychiatric units and therefore are presumably under the care of psychiatrists, a substantial proportion of general hospital psychiatric inpatients are treated outside psychiatric units, in so-called scatter beds (23). Nonpsychiatrist physicians commonly serve as the attending physicians for psychiatric patients in scatter beds (24). The reported patterns of test utilization reflect a summation of the test-ordering practices in unit-based and scatter bed settings.

Medical expenses are, for the most part, directly under the control of physicians (25). To curtail indiscriminate ordering of tests, policy makers have devised a series of cost-containment strategies that focus on the test-ordering practices of physicians. Some of these strategies involve overt rationing and risk-sharing plans (26).

In the area of neuropsychiatric diagnostic procedures in general hospitals, there is little evidence of widespread unnecessary testing. The provision of these tests to general hospital psychiatric inpatients is highly selective and closely related to clinical variables. Attention should now be focused on defining with greater precision the clinical indications and usefulness of such testing for psychiatric inpatients.

Effect of Instructional Cues on Schizophrenic Patients' Performance on the Wisconsin Card Sorting Test

Robert S. Goldman, Ph.D., Bradley N. Axelrod, Ph.D.,
and Lauren M. Tompkins, Ph.D.

***Objective:** Schizophrenic patients are particularly deficient on measures of executive functioning, notably the Wisconsin Card Sorting Test. This study was conducted to determine the efficacy of a cuing strategy in facilitating performance on this cognitive measure of the integrity of prefrontal brain structures and functioning. **Method:** Twenty-four schizophrenic inpatients and 24 demographically matched inpatients with mood disorders were administered the Wisconsin Card Sorting Test either with instructional cues at the beginning of the task or with the standard administration procedure. **Results:** There was a significant benefit of cues for the patients with affective disorders as well as for the schizophrenic patients. The schizophrenic subjects in the uncued condition maintained poor but stable performance throughout the course of the task. **Conclusions:** The study suggests that the deficit in executive functioning of schizophrenic patients may lie in the formation of concepts, not in their application.*

(Am J Psychiatry 1992; 149:1718-1722)

Deficient cognitive functioning is a well-documented phenomenon in schizophrenia (1, 2). Recent advances in neuroradiological techniques have confirmed frontal lobe dysfunction in schizophrenia; varying degrees of hypofrontality have been found on measures of both structure and functioning—magnetic resonance imaging (MRI) and regional cerebral blood flow (3–6). While many neuropsychological studies have demonstrated generalized, nonspecific cognitive impairment in schizophrenic subjects relative to normal control subjects (7–9), other studies have shown the presence of more specific neuropsychological dysfunction in schizophrenia, namely, impairment in executive functioning (10, 11). Abilities that reflect executive functioning include planning, sequencing, concept formation, cognitive set shifting, and cognitive set maintenance (12). Executive functions are thought to be mediated primarily by the prefrontal cortex (13, 14).

The Wisconsin Card Sorting Test has been extensively used as a measure of executive functioning. Non-schizophrenic patients with focal frontal lesions per-

form poorly on this task relative to other brain-injured patients with nonfrontal lesions and normal control subjects (15–17). Performance by schizophrenic patients on the test typically reveals more perseverative errors, more perseverative responses, and fewer obtained categories in comparison to other psychiatric patients and nonpsychiatric control subjects (18–20).

Several researchers have used the Wisconsin Card Sorting Test to examine whether training can improve executive functioning performance in severely impaired schizophrenic populations. Stuss and Benson (13) modified the standard 128-card test procedure by including instructional intervention after the first 64 cards had been presented. The instructional intervention varied from the traditional administration of the test by informing the patients of the sorting principles and also informing them that the sorting principles change throughout the course of the task. Following the instructional intervention, the performance of leukotomized schizophrenic subjects did not improve with the second deck of cards, whereas the performance of the normal subjects did. Recent studies using the Stuss modification with nonleukotomized but chronic, medicated schizophrenic patients have reported a similar inability of these patients to profit from instructional feedback. Card-by-card instruction on the Wisconsin Card Sorting Test (21, 22) failed to produce an enduring learning effect after termination of instruction. Bellack et al. (23) also provided intensive instructional training on the test for a less chronic schizophrenic population and found that cuing plus a monetary incentive produced stable improvement in performance,

while the incentive alone failed to alter performance. However, these results are unclear. The absence of a condition in which there was instructional intervention and no monetary incentive does not allow attribution of the effects of learning to cuing alone.

The present study was undertaken to examine the extent to which schizophrenic subjects, in contrast to psychiatric comparison subjects, respond to external intervention in the form of cuing to improve performance on the Wisconsin Card Sorting Test. A criticism of previous training studies with schizophrenic subjects has been the lack of nonschizophrenic psychiatric comparison subjects, who provide demographic comparability (i.e., in effects of hospitalization and presence of psychopathology). Furthermore, previous research (22, 23) initiated training after the completion of an uncued block of trials rather than at the outset, when the patients were still naive about the task. The initiation of cuing after completion of several trials may have created a cognitive schema that altered subsequent performance, thereby confounding the effects of cuing. In this study we initiated training at the beginning of the Wisconsin Card Sorting Test in an effort to evaluate the effectiveness of priming for patients who had not developed a cognitive set based on previous exposure to the test.

METHOD

The study group consisted of 48 male patients hospitalized in the general psychiatric units at a Department of Veterans Affairs medical center. Twenty-four patients met the *DSM-III-R* criteria for schizophrenia, and 24 met the criteria for mood disorders (11 had bipolar disorder and 13 had a major depressive episode). Diagnoses were formulated on the basis of independent clinical interviews conducted by a three-member psychiatric team. Final diagnoses for the patients included

in the study required unanimous consensual validation. Exclusion criteria consisted of a history of neurological injury or illness unrelated to the psychiatric diagnosis and alcohol or drug abuse as defined by *DSM-III-R*.

The study group had a mean age of 37.9 years (SD=7.7) and a mean education level of 11.6 years (SD=1.1) (table 1). The schizophrenic patients' mean age at onset was 21.2 years (range=17–29 years). Table 1 presents demographic information and scores on the vocabulary subtest of the WAIS-R (an estimate of verbal intellectual functioning) and the Mini-Mental State examination (24). The four subgroups did not differ with respect to age, education, vocabulary, and performance on the Mini-Mental State examination. A main effect of diagnostic group was found for scores on the Brief Psychiatric Rating Scale (BPRS) (25), a measure of psychopathology. As shown in table 1, both schizophrenic subgroups had higher BPRS scores than did the patients with affective disorders. Within each diagnostic group, BPRS scores did not differ between the cued and the standard administration conditions. Furthermore, BPRS scores failed to correlate significantly with the dependent measures. The patients with schizophrenia were receiving neuroleptic and anticholinergic medications. The chlorpromazine-equivalent dose did not differ between subjects in the standard administration condition (mean=890, SD=1354) and those in the cued condition (mean=796, SD=1122).

After diagnosis and entry into the study, subjects within each diagnostic group were randomly assigned to one of the two experimental conditions: standard and cued administrations of the Wisconsin Card Sorting Test. In all conditions two identical decks of 64 response cards (26) were used. The test consists of four stimulus cards, each containing shapes that differ in terms of color, form, and number. The subject is required to sort 128 response cards according to each of three principles (color, form, and number), which are changed surreptitiously following 10 accurate sorts.

FIGURE 1. Cumulative Perseverative Errors on Eight-Card Blocks of the Wisconsin Card Sorting Test for Schizophrenic Patients and Patients With Affective Disorders in Cued and Uncued Conditions

^aR²=0.998.

^bR²=0.996.

^cR²=0.994.

^dR²=0.998.

"Perseveration" on this measure refers to an inability to recognize that a change in sorting principle (color, form, number) has been introduced, so that the patient continues to sort according to the previously correct principle despite external feedback. "Categories obtained" indicates the number of successfully learned principles out of a possible six category sorts (color, form, number, color, form, number).

In the standard administration condition, subjects were informed only of the accuracy of their responses ("correct" or "incorrect") through verbal feedback. In the cued condition, adapted from Goldberg et al. (22), subjects were informed of the three possible sorting principles at the outset. They were also informed that the principles could change at any time but were not told explicitly when the change would occur (i.e., after 10 correct sorts). These instructions were repeated for every 32 cards, a total of four times. In this study all 128 response cards were administered.

RESULTS

A 2x2 (Diagnostic Group by Administration Condition) factorial analysis of variance (ANOVA) was performed for five of the six established Wisconsin Card Sorting Test measures (26). Total correct was not studied, since the analyses would be identical to those for total errors. The dependent variables included total errors, perseverative responses, perseverative errors, non-perseverative errors, and number of categories obtained (table 1). Significant main effects for administration condition were observed for total errors and perseverative responses. Post hoc one-way ANOVAs revealed significantly better performance for the primed condition relative to the standard administration. Neither significant interactions nor main effects for diagnostic

groups were observed on these variables. No main effects or interaction effects were observed for nonperseverative errors and categories obtained.

Although no significant differences between diagnostic groups were found for perseverative errors, there was a significant main effect for instructional condition (table 1) and a Diagnosis by Instruction interaction ($F=4.00$, $df=1, 44$, $p<0.05$). Again, the performance of individuals in the cued condition was superior to that of those in the uncued condition. In addition, post hoc analyses showed that the schizophrenic subjects benefited the most from instructional cues.

Hotelling's T multivariate ANOVA with repeated measures was performed on the five Wisconsin Card Sorting Test measures between the administration of the first deck of 64 response cards and the administration of the second deck. The analyses revealed no significant difference between the subject groups in responses for the two decks ($F=0.49$, $df=18, 111$, $p>0.05$, multivariate approximation to Wilks's lambda). This suggests that performance on the test remained comparable over time for the diagnostic groups, regardless of whether they received cues. However, this analysis is not sensitive to fluctuations in performance over the course of the task.

To examine more closely the performance trends for each subject group, perseverative error scores for eight-card blocks were cumulatively totaled; these are graphically presented in figure 1. The perseverative error measure was chosen because this variable was not only sensitive to instructional set but also differentiated the patients with mood disorders from the schizophrenic patients in terms of their ability to benefit from cuing. Figure 1 illustrates the obviously inferior performance of the uncued schizophrenic subgroup. Inspection of the cumulative curves further reveals that performance did not change over the course of the task for any of the subgroups. Lines of best fit and regression coefficients (figure 1) were computed for each subgroup and statistically demonstrated no deviation from a straight line. Furthermore, matched-pairs t tests were performed on several consecutive eight-card blocks (i.e., for blocks 4, 8, and 12) to examine whether changes in performance occurred consequent to the administration of instructional cues. As expected, no significant differences between consecutive block pairs were found across all four subgroups.

DISCUSSION

This study demonstrated subjects' significant improvement in performing a task of executive functioning when they were provided with cues before beginning the task. Improved performance on the Wisconsin Card Sorting Test was found for individuals with mood disorders and individuals with schizophrenia, with the schizophrenic patients showing the greatest improvement on perseverative errors. Performance on the test in the cued and uncued conditions was unrelated to se-

verity of illness. These findings strongly contrast with those obtained by Goldberg et al. (22), who found that explicit card-by-card instruction only transiently improved performance. The differences in findings may possibly be explained by the nature of the Goldberg et al. subject group, which was composed of persons with chronic, unremitting schizophrenia. The schizophrenic group in our study was more similar to that of Bellack et al. (23), who reported significant benefits of cuing in the context of monetary incentives.

With regard to the quality of instruction, Bellack et al. (23) provided comprehensive explanations of the Wisconsin Card Sorting Test by identifying the sorting rules, providing information pertaining to change of set, and giving a card-by-card explanation of decision rules for the first five response cards. Using a less involved technique at the beginning of the task, we found a similarly strong effect of cues. Subjects in this study were informed of the sorting principles, alerted to the possibility of change without any card-by-card instruction, and provided repetition of instructions only at 32-card intervals. On the surface, this suggests that the impairment of executive functioning is not so severe as to preclude learning the test with a minimum of external intervention. However, the timing of the cues may be critical in the effectiveness of the intervention technique. Consistent with previous research in our laboratory (27), inability of schizophrenic patients to generate and shift cognitive sets occurs at the beginning of the Wisconsin Card Sorting Test and is maintained throughout the task. This may result from incorporation of an invariant, and inaccurate, internal response structure by schizophrenic patients. It appears that once a cognitive set is incorporated, schizophrenic subjects have little difficulty in maintaining that particular set. In fact, even if the formulated schema is inaccurate, schizophrenic subjects will persevere in that set despite negative response feedback. Early instructional priming may therefore provide an accurate response structure, or schema, upon which schizophrenic persons can rely in performing the task, without the need for more elaborate intervention.

If indeed performance on the Wisconsin Card Sorting Test is predicated on maintenance of an established cognitive structure, even if that schema is inaccurate, then the performance of all individuals should not vary over the course of the task. In this study, we found that the schizophrenic subjects and the subjects with affective disorders maintained stable response sets over the course of the test regardless of whether they were cued. This was clearly demonstrated by the consistency of performance in the two halves of the task and the invariant lines of best fit for the perseverative error measure (figure 1). The finding of stable performance suggests that the generation and implementation of cognitive schemas are separate functional entities. Effective performance on the Wisconsin Card Sorting Test as a measure of executive functioning relies on generation and revision of schemas as well as maintenance of those schemas. On the basis of the finding that

schizophrenic subjects are readily able to maintain schemas, one could hypothesize that the so-called neurobehavioral frontal lobe deficit in schizophrenia lies in the formulation of an accurate cognitive schema, not in its implementation. Deficits in self-monitoring and ability to regulate self-initiated behavior have theoretically been linked to frontostriatal dysfunction in schizophrenia (28, 29). The fact that the patients with affective disorders and the schizophrenic patients benefited from being cued indicates that the cuing paradigm served to provide both groups with an accurate cognitive structure with which they could effectively maintain performance, reducing the self-monitoring component of the task. These findings also suggest that memory per se is not the primary functional component underlying performance deficits of schizophrenic patients on the Wisconsin Card Sorting Test, since memory deficits would be more critical to the maintenance of a response structure than to its generation.

It remains to be seen whether performance on tasks purported to be measures of executive functioning are in fact mediated exclusively by the frontal lobes or require input from other cortical regions, such as the temporal region (30-32). The notion that multiple cognitive processes and cortical sites may be involved in performance on measures of executive functioning certainly deserves further examination.

Physical and Sexual Abuse Histories Among Children With Borderline Personality Disorder

Stuart J. Goldman, M.D., Eugene J. D'Angelo, Ph.D., David Ray DeMaso, M.D.,
and Enrico Mezzacappa, M.D.

***Objective:** The purpose of the study was to determine whether a history of physical or sexual abuse is more common in children with borderline personality disorder than in other children evaluated in the same outpatient psychiatric clinic. **Method:** The authors contrasted rates of abuse in 44 children diagnosed with borderline personality disorder and in 100 comparison children. **Results:** The borderline personality disorder group had a significantly greater prevalence of physical and combined physical/sexual abuse. Sexual abuse rates alone did not differ significantly between groups. **Conclusions:** The finding of greater abuse in the group with borderline personality disorder supports the hypothesis that a history of trauma is associated with the disorder.*

(Am J Psychiatry 1992; 149:1723-1726)

Borderline personality disorder has received extensive attention in the adult and child clinical literature (1-8). Through use of *DSM-III-R* criteria, borderline personality disorder has been shown to be a valid and reliably diagnosed syndrome (9, 10) with serious, long-term emotional and behavioral consequences (11).

While diagnostic criteria have been improved, there is little consensus regarding the cause of the disorder. Psychodynamic, family, and biologic etiologies have been hypothesized (12-15). Recently, reports of a 60%-80% prevalence of childhood abuse, particularly sexual abuse, in adults with borderline personality disorder have emerged (16-18). It has been noted that the prevalence of sexual abuse differentiates patients with borderline personality disorder from comparison groups in both inpatient and outpatient psychiatric settings (17, 18). On the basis of these findings, Herman and van der Kolk (19) have hypothesized that psychological trauma, specifically abuse, plays an important role in the genesis of borderline personality disorder. They speculated that borderline personality disorder has symptomatic parallels with posttraumatic stress disorder (PTSD).

In contrast, the reports of childhood abuse in the histories of children with borderline personality disorder have been limited in nature and have tended to be confined to case reports (6, 7). Bemporad et al. (6) re-

ported a higher than average prevalence of physical abuse among their sample of 24 children with borderline personality disorder who were evaluated in an inpatient setting. Grapentine et al. (unpublished 1990 paper) noted a greater than average prevalence of sexual abuse among hospitalized adolescent girls diagnosed with borderline personality disorder. Most recently, Famularo et al. (20) have described trauma and PTSD in a sample of 19 children with borderline personality disorder.

The present study sought to determine whether a history of physical or sexual abuse is more common in children with borderline personality disorder than in other children evaluated in the same outpatient psychiatric clinic. This investigation reports on a much larger and younger group of children with borderline personality disorder than has previously appeared in the literature.

METHOD

The study was conducted in the outpatient psychiatry clinic of a tertiary care pediatric hospital. Patients were referred from a wide range of sources within and outside the hospital. The child and family member or caregiver each underwent a 1-hour diagnostic interview. Semistructured interviews were conducted by a staff psychiatrist, psychologist, social worker, or child psychiatry resident. The interview used a standard format to generate information in the following areas: current behavior and symptoms of the child; medical, educational, developmental, and family histories; and mental status examination.

Received Nov. 6, 1991; revision received March 11, 1992; accepted April 10, 1992. From Children's Hospital and Harvard Medical School, Boston. Address reprint requests to Dr. Goldman, Department of Psychiatry, Children's Hospital, 300 Longwood Ave., Boston, MA 02115.

TABLE 1. DSM-III-R Criteria for Borderline Personality Disorder Adapted to Account for Developmental Differences in Childhood

Adult Criterion	Adapted Childhood Criterion	Examples
1. A pattern of unstable and intense interpersonal relationships characterized by alternation between extremes of overidealization and devaluation	A pattern of unstable and intense interpersonal relationships characterized by alternation between extremes of overidealization and devaluation and/or marked distortion of the nature of the relationship	Describing teacher as a "girlfriend," chronic inability to maintain friendships despite wish to do so
2. Impulsiveness in at least two areas that are potentially self-damaging, e.g., spending, sex, substance use, shoplifting, reckless driving, binge eating (do not include suicidal or self-mutilating behavior covered in item 5)	Impulsiveness in at least two areas that are potentially self-damaging, e.g., reckless risk taking, running away, stealing, substance abuse, sex, binge eating	Walking across railroad bridge railing, sniffing glue
3. Affective instability: marked shifts from baseline mood to depression, irritability, or anxiety, usually lasting a few hours and only rarely more than a few days	Affective instability: marked, rapid shifts from baseline mood to depression, irritability, or anxiety lasting less than a few hours and only rarely more than a few days. Episodes may include transient distortions of reality	Early-afternoon anxiety attack with persecutory delusions, followed by successful participation in soccer game in late afternoon
4. Inappropriate, intense anger or lack of control of anger, e.g., frequent displays of temper, constant anger, recurrent physical fights	Inappropriate, intense anger or lack of control of anger, e.g., frequent displays of temper, constant anger, recurrent physical fights	Easily provoked, frequent fights, threatens and attempts to throw therapist out window
5. Recurrent suicidal threats, gestures, or behavior or self-mutilating behavior	Recurrent suicidal threats, gestures, or behavior or self-mutilating or self-endangering acts	Carves boyfriend's name into arm, multiple episodes of being struck by car
6. Marked and persistent identity disturbance manifested by uncertainty about at least two of the following: self-image, sexual orientation, long-term goals or career choice, type of friends desired, preferred values	Marked and persistent disturbance in self-perception and -presentation characterized by confusion regarding two of the following: gender identity or roles, friendships, socially appropriate behaviors, school or career plans, self-image	Chronic cross-dressing, running for class president despite having no friends
7. Chronic feelings of emptiness or boredom	Chronic feelings of emptiness or boredom	Chronic complaints of boredom, unable to invest in appropriate activities
8. Frantic efforts to avoid real or imagined abandonment (do not include suicidal or self-mutilating behavior covered in item 5)	Frantic efforts to avoid or major preoccupation with real or imagined abandonment (do not include suicidal or self-mutilating behavior included in item 5)	Continual concern that therapist will not be there at next appointment, refusal to leave house while parent is at work

The interview data were reviewed at the time of the diagnostic session by an interdisciplinary team headed by the first author. A consensus diagnosis was made for all subjects according to *DSM-III* or *DSM-III-R* criteria. In cases in which patients had been diagnosed before the *DSM-III* revision, all relevant records were reviewed to determine whether patients met the *DSM-III-R* criteria. All subjects in this study maintained their initial diagnosis after this careful record review.

Subject Selection

Table 1 presents *DSM-III-R* criteria for borderline personality disorder that were adapted to account for developmental differences across childhood. From just under 2,000 consecutive subjects evaluated since 1982, all subjects who received a definite or probable diagnosis of borderline personality disorder were selected for the study. A diagnosis of definite borderline personality disorder was made when a child met at least five of the eight *DSM-III-R* criteria. A diagnosis of probable borderline personality disorder was made when a child met at least four of the criteria. The group with a probable diagnosis of borderline personality disorder was included in this study on the basis of Clarkin et al.'s finding (21) that the presence of four of the symptom crite-

ria makes the diagnosis of borderline personality disorder highly likely.

The convergent validity of the two groups was also demonstrated by using the Diagnostic Interview for Borderline Patients—Record Review (DIB-R) (22). Each record was reviewed in a blind manner and cumulative DIB-R scores were derived (23). The analysis indicated that the entire group with a definite diagnosis of borderline personality disorder and 17 of the 22 subjects with a probable diagnosis were at or above the DIB-R cutoff score of 7. Of the five remaining children in the group with a probable diagnosis, four were 1 point and the fifth subject was 2 points below the cutoff score.

A comparison group of 100 subjects was randomly selected from patients who received diagnostic evaluations in the outpatient clinic concurrently with the study group. They all underwent the same diagnostic process and clinical review as described for the study group and had a wide range of diagnoses other than borderline personality disorder.

Subjects

Of the 44 children in the group with borderline personality disorder, 32 were boys (mean age=10.8 years,

SD=3.6) and 12 were girls (mean age=12.4, SD=4.5). The families' mean Hollingshead and Redlich occupation score (24) was 4.6 (SD=1.5). The comparison group consisted of 62 boys (mean age=9.9 years, SD=4.3) and 38 girls (mean age=10.0 years, SD=3.8). Their families' mean Hollingshead and Redlich occupation score was 5.1 (SD=1.8). There were no significant differences in age, sex, or families' occupation scores for the two groups.

Assessment of Childhood Abuse

The semistructured interview data were reviewed for each subject to identify the presence or absence of childhood physical or sexual abuse histories obtained during the diagnostic assessment. It was noted that the subjects had been abused only when clear data, such as physical evidence or direct statements by the child, parent, or protective agency, were obtained. Cases in which abuse was possible or even probable but in which there was no substantiating data were not considered cases of abuse for this study. None of the subjects in cases of abuse was embedded in the complex context of custody, visitation, or divorce disputes, a context that might diminish the validity of the complaint.

RESULTS

Seventeen of the 44 children with borderline personality disorder (38.6%) and nine of the 100 clinical comparison children (9%) had an abuse history. The complex chi-square analysis revealed that the children with borderline personality disorder had a significantly greater frequency of abuse than did the comparison group ($\chi^2=25.5$, $df=3$, $p<0.001$). The contingency coefficient of 0.4 reflected this association between diagnosis and abuse status. Using the test for the significance between proportions, we found that the group with borderline personality disorder had significantly greater rates than the comparison group of both physical abuse (five versus three subjects; $z=2.1$, $p<0.05$) and combined physical/sexual abuse (seven versus no subjects; $z=4.0$, $p<0.05$). The prevalence of sexual abuse did not differ significantly between the two groups (five versus six subjects; $z=1.0$, *n.s.*).

When the group was divided according to the categories of probable and definite borderline personality disorder, no significant difference in the frequency of abuse was observed ($\chi^2=2.5$, $df=3$, *n.s.*). Similarly, when the subjects with borderline personality disorder were divided according to sex, no significant difference in frequency of abuse was noted ($\chi^2=2.4$, $df=3$, *n.s.*).

DISCUSSION

These results indicate that the prevalence of abuse is significantly greater in children diagnosed with borderline personality disorder than in other children who

come for clinical services in an outpatient psychiatric department. We have demonstrated this in a systematic manner, with a much larger and younger cohort than previously reported. The children with borderline personality disorder had significantly greater rates of both physical and combined physical and sexual abuse. However, there was no significant difference between groups in the prevalence of sexual abuse alone.

These findings correspond to studies of borderline personality disorder in adults in which a history of childhood abuse is common. However, the prevalence of abuse in the present cohort (38.6%) is less than that found in the adult studies, which report rates of between 60% and 80%. A number of possibilities may account for the lower prevalence. First, the information about abuse history was obtained from both the children and families as part of a general psychiatric evaluation in which abuse was not the referring complaint. Since abusive families tend to be secretive about these activities and children are often forced into silence (25), the lower prevalence may be a reflection of significant underreporting. Second, most (73%) of the patients with borderline personality disorder who participated in this study were male. While this is a typical pattern for school-age children referred for psychiatric disorders (26), it contrasts with the largely female samples reported in most studies of adult patients with borderline personality disorder. Given the differences in the reported prevalence of sexual abuse among female and male children (a ratio of 3:1), it is likely that the preponderance of boys in the cohort resulted in a lower overall rate of documented sexual abuse than that in an adult, predominantly female population with borderline personality disorder. Finally, it is likely that the effects of traumatic abuse have both short- and long-term sequelae for children. These effects might include the propensity to develop the disorder at a later date or the lower likelihood of improvement in the subpopulation of children with borderline personality disorder who have been abused. Both of these possibilities would increase the rate of abuse found in a cohort of adults with borderline personality disorder.

The validity of reported abuse has been the subject of professional and lay commentary for many decades. In child populations, the child's validity and credibility as a reporter have been described by several authors (27, 28). Particular controversy exists when the child is in a custody, divorce, or visitation dispute (29). None of our abused study or comparison group members were in such a dispute. The validity of the cases of abuse in the present study was substantiated by the internal and external consistency, internal detail, and interview process, as suggested by Nurcombe (27). While we felt that emotional abuse or the witnessing of abuse might play a role in the genesis of the disorder, the definitions and reporting of these were considered too subjective to be included in this study.

While a history of abuse was associated with the diagnosis of borderline personality disorder in this group of children, the study did not examine other possible

risk factors, such as parent-child interactions, comorbidity, or temperament, which might also influence psychological development and functioning. The delineation of an etiologic hypothesis that explains the interaction of important risk factors in the development of borderline personality disorder remains to be articulated and evaluated. The significant percentage of patients with borderline personality disorder who have no known abuse or biological diathesis and have been reportedly reared in supportive environments also warrants further explanation. Continued detailed and longitudinal studies are indicated in order to understand borderline personality disorder. However, what remains quite noteworthy is our finding that children with borderline personality disorder, like adults and adolescents with borderline personality disorder, have a significantly greater rate of histories of abuse than their peers. This makes the evaluation of the etiologic impact of abuse a compelling place to start and further emphasizes the parallels between borderline personality disorder and PTSD.

Lithium-Discontinuation-Induced Refractoriness: Preliminary Observations

**Robert M. Post, M.D., Gabriele S. Leverich, M.S.W.,
Lori Altshuler, M.D., and Kirstin Mikalauskas, B.S.**

The authors used a systematic life-chart methodology to observe four patients with bipolar disorder in whom long periods (6–15 years) of effective lithium prophylaxis were followed by relapses on lithium discontinuation. Once the drug was reinstituted, it was no longer effective. The incidence, predictors, and mechanisms underlying this phenomenon all require further systematic study. The current preliminary observations suggest an additional reason for caution when lithium discontinuation in the well-maintained patient is considered.

(Am J Psychiatry 1992; 149:1727–1729)

Relapses following lithium discontinuation have helped establish its efficacy in prophylaxis (1–3). In the studies of Baastrup et al. (1) and in many subsequent studies, it appeared that almost all of the patients responded positively to reinstitution of lithium treatment. We have found, based on systematic life charting of four patients, that this positive response to reinstitution of lithium treatment may not always occur.

METHOD

The four patients were diagnosed according to *DSM-III-R* criteria as having bipolar disorder. The previous course of illness and response to medication of each patient was graphically reconstructed retrospectively and prospectively by applying systematic life-chart criteria, described elsewhere (4). Briefly, this involved assessing and charting previous episodes of depression and mania rated as reflecting mild (none), moderate (substantial), or severe (complete) functional incapacity in social or occupational roles. This was accomplished with the assistance of interviews of the patients and their family members as well as review of hospital and physicians' records. Three patients were studied before and/or after

an inpatient admission, and one was examined in an outpatient consultation setting.

RESULTS

In all four patients, after periods of successful lithium prophylaxis ranging from 6 to 15 years, discontinuation of treatment was associated with the occurrence of relapses and the subsequent failure to respond to lithium at similar or higher doses after it was reintroduced. Multiple adjunctive treatments were also employed without success. A brief vignette of one patient's experience is summarized and illustrated in figure 1 and was typical of the experience of the other patients.

The patient whose course is shown in figure 1 was a 43-year-old married woman with five children. She experienced the onset of her illness at the age of 29, when a severe depressive episode was followed by mild hypomania lasting 5–6 weeks. After three more cycles, she was given 900 mg/day of lithium carbonate; after this she did not cycle into her usual hypomanic phase. She remained symptom free for the next 8½ years while receiving lithium maintenance treatment. Her illness reemerged 1½ years following discontinuation of lithium; she experienced an incapacitating depression, virtually identical to her initial episodes. Within days of onset of this episode, she was given 900 mg/day of lithium, but she did not respond and continued to cycle despite ongoing lithium therapy for the next 2 years.

Received Aug. 30, 1991; revision received April 6, 1992; accepted April 24, 1992. From the Biological Psychiatry Branch, National Institute of Mental Health. FIGURE 1. Treatment Refractoriness Induced by Lithium Discontinuation in a Patient With Bipolar Disorder

Augmentation of lithium with fluoxetine and alternative trials of other agents (protriptyline, bupropion, isocarboxazid, valproic acid, carbamazepine, and a course of ECT) were all unsuccessful in stopping the recurrence of the disabling depressive cycles.

The three other patients were 67-, 34-, and 52-year-old women with bipolar I disorder who experienced periods of stability lasting 5, 6, and 15 years, respectively, while receiving lithium. Each failed to re-respond once lithium treatment was reintroduced after discontinuation and the emergence of a new episode.

DISCUSSION

These four patients appear to share the common phenomenon of having a period of sustained and successful prophylactic response to lithium terminated by dose reduction or drug discontinuation. In all four patients, after their illness reappeared and lithium therapy was resumed, adequate control over their episodes was not again achieved. It is highly unlikely that the illness would have spontaneously run this course in the absence of the initial lithium-related intervention and its subsequent discontinuation. While taking lithium, all of these patients sustained remissions substantially longer than their previous well intervals. The refractory nature of the recurrences of episodes in these patients after lithium discontinuation and reinstitution suggests the possibility that biological changes occurred when these patients experienced a reemergence of episodes after lithium discontinuation and that these changes were associated with lithium nonresponsiveness. In the studies of Gelenberg et al. (5) and O'Connell et al. (6), a history

of more than three or four previous episodes was associated with a poor response to lithium, suggesting that the occurrence of an additional episode itself may have negative prognostic implications.

It is of interest that one of the patients responded to reinstitution of lithium following the first discontinuation of lithium when she was 21 years old, but not following the second discontinuation of lithium when she was 28. These data raise the possibility that, in some instances, repeated occurrences of lithium discontinuation and reemergence of episodes may be associated with the induction of lithium refractoriness. This could provide an additional basis for the occurrence of lithium refractoriness in patients with periodic non-compliance (2); i.e., repeated discontinuations might produce multiple exacerbations, ultimately generating refractoriness.

From a clinical perspective, these preliminary data, based on detailed life-chart observations, emphasize the importance of further systematic exploration of this phenomenon. In a larger series of inpatients who had had previous trials of lithium of at least 1 year's duration and who were referred to our institute because of refractory bipolar illness, nine (13.6%) of 66 patients showed clear-cut (N=7) or possible (N=2) evidence of discontinuation refractoriness. Other clinicians (J. Angst, personal communication, December 1989; A. Kukopulos, T. Hahn, and G.M. Goodwin, personal communication, June 12, 1991) have also seen patients reflecting this phenomenon of drug refractoriness following lithium discontinuation. For example, Goodwin's patient had an entirely symptom-free period of 10 years while receiving lithium. Following discontinuation of the drug and a severe depressive relapse 6

months later, the patient immediately started to take lithium again. Despite this, severe depressions (three requiring hospitalization) continued and the patient committed suicide. Such observations of the emergence of lithium refractoriness following discontinuation-related episodes may provide another reason (in addition to the risk of relapse) for conservatism when the physician and patient are considering the potential risks and benefits of a trial of lithium discontinuation.

Side Effects and the "Blindability" of Clinical Drug Trials

Kerrin White, M.D., Judith Kando, Pharm.D., Teron Park, B.A.,
Christine Waternaux, Ph.D., and Walter A. Brown, M.D.

A novel, simple approach to retrospective assessment of "blindability" was applied to data on outpatients in a controlled, double-blind clinical comparison of a putative antidepressant, etoperidone, and placebo. A "blind" evaluator proved capable of discriminating between the active drug and placebo on the basis of reported side effects alone, raising questions about the true blindness of the study.

(Am J Psychiatry 1992; 149:1730-1731)

Double-blind procedures, in which drugs and placebo are coded and dispensed in identical-appearing capsules so that supposedly neither the subject nor the evaluator/treater knows which treatment is being given, have become a standard in clinical research. They are thought to remove the factor of investigator or subject bias in determining outcome. However, many clinical researchers are well aware that on the basis of side effects alone, subjects taking active drugs can often be distinguished from those taking placebo. This may be more true of psychotropic medications than of other medications such as vitamins or antibiotics because of psychotropic medications' numerous side effects.

Some previous researchers (1-4) have documented this problem and called for incorporation of procedures to assess blindness as part of the research protocol. However, this is hardly ever done or reported, perhaps because such inquiry might seem to risk invalidating results. Therefore, we devised an approach to assessment of the potential blindness of a comparative drug trial that can be applied after a study is completed, without requiring any initial planning for this in the original study methodology. Our approach was simply to provide an informed but blind evaluator with data on side effects and dosage for each subject, without reference to therapeutic effects, and to ask the evaluator to guess the treatment assignment. To avoid the aforementioned risk of appearing to invalidate results of importance to other parties, we chose to use data from a previously unpublished study of a drug that is no longer intended for marketing. Our study adds to the earlier

literature on the "unblinding" of studies by using the strategy of keeping the evaluator blind to the therapeutic effects of the treatment. Also, by using data collected years earlier, our study demonstrates the feasibility of applying this procedure to databases that are relatively remote from the current investigators.

METHOD

The data on which this study was conducted were derived from a seven-site, multicenter, double-blind three-arm comparison of two doses of etoperidone, a trazodone-like prospective antidepressant, and placebo in outpatients with major depression. Data from two sites (Belmont, Mass., and Providence, R.I.) were analyzed according to the following protocol.

Completed case report forms were reviewed by one of us (K.W.), who deleted all information pertaining to the therapeutic effects on the patients' depression and any conjectural attribution of side effects to treatment recorded by the original study assessor. This resulted in modified case report forms that described each subject in terms of that subject's initial depressive symptoms, medical history, dosage, and side effects but omitted mention of therapeutic effects during the trials. These forms were then given to the study evaluator (J.K.), who reviewed them and guessed whether each subject had received a high dose of etoperidone, a low dose of etoperidone, or placebo and made an estimate of confidence in this guess. The evaluator, a clinical pharmacist, had reviewed the investigator brochure distributed prior to the study and thus was aware of the anticipated side effects of etoperidone. In two cases in which subjects dropped out after a single evaluation while they were on the double-blind medication regimen, she declined to make any guess because of insufficient information. The data we report concern the 34 subjects, 13 in Belmont, Mass., and 21 in Providence, R.I., for whom the evaluator made a guess about treatment assignment.

Received Jan. 14, 1992; revision received March 23, 1992; accepted April 17, 1992. From the Department of Psychiatry, Providence VA Medical Center; the Department of Psychiatry, Brown University School of Medicine, and Clinical Programs, Ltd., Providence, R.I.; and McLean Hospital, Belmont, Mass. Address reprint requests to Dr. White, Department of Psychiatry, Providence VA Medical Center, 830 Chalkstone Ave., Providence, RI 02908.

Supported in part by a grant from McNeil Pharmaceutical.

RESULTS

When the subjects taking the two dosages of etoperidone were combined into one active drug group and their data were compared with the data on the placebo group, the evaluator correctly guessed active drug assignment for 73% (N=16) of the 22 etoperidone-treated subjects and correctly guessed placebo assignment for 67% (N=8) of the 12 placebo-treated subjects. The hypothesis of independence between actual and guessed treatment assignment was rejected by use of Fisher's exact test for the four entries ($p=0.04$). Thus, the evaluator guessed more accurately than predicted by chance whether subjects received active drug or placebo; the kappa coefficient of agreement (5) was 0.38 ($SD=0.16$). She was not successful in differentiating the two dosage levels of active etoperidone ($kappa=0.03$, $SD=0.12$).

When the evaluator correctly guessed the treatment assignment, she considered herself "absolutely certain" or "quite certain" (versus the alternatives of "moderately certain" or "not certain") in the majority of cases (13 of 24, or 54%), whereas when her guesses proved incorrect, she considered herself this certain in four (40%) of 10, a nonsignificant difference suggesting limited ability to gauge correctly the reliability of her guesswork.

DISCUSSION

Those who have firsthand familiarity with conducting controlled psychopharmacology research will not be surprised that our "blind" evaluator was able to guess double-blind treatment assignment successfully on the basis of side effects alone for about three-quarters of the subjects. In fact, this is not a new finding, but it represents a potential defect in research methodology that is rarely addressed in reports of such drug trials.

Our approach is novel in that it allows an independent investigator, far removed from the original study, to retrospectively assess "blindability" of the treatment comparison under study. This suggests that numerous existing studies could be used to make a similar examination of this issue. Also, results of various studies could be combined to investigate whether the magnitude of treatment effects is greater with the drugs and the treatment comparisons that are most readily rendered "unblind" by side effects. For example, a recent meta-analysis of the efficacy of antiobsessional antidepressants suggested stronger effects for an older serotonergic antidepressant, clomipramine, with more diverse neuropharmacological effects (and side effects) than for newer antidepressants, such as sertraline and fluvoxamine, with more selective serotonergic effects and there-

fore fewer side effects (6). This result was interpreted as suggesting the importance of nonserotonergic mechanisms in antiobsessional effects, but it could merely represent the greater "unblindability" of clomipramine because of side effects.

Also, we must consider the possibility that investigators with strong biases for or against specific treatments are not fully protected by the double-blind procedure against unwittingly affecting results of their studies. The blind may be better maintained if a separate investigator assesses therapeutic effects only, without knowledge of side effects; but even then, the subject, through his or her knowledge of probable treatment assignment, may carry the effect of "unblinding" on outcome expectations. Additional methodological safeguards, such as rating symptoms before side effects, may help, but they are susceptible to the same problem. "Active" placebo treatments that mimic certain side effects may also help maintain the blind, but sometimes improvement that occurs with such treatment may raise the possibility of active psychotherapeutic effects where they were not anticipated. Of course, in some trials, depending on the severity of side effects and how different they are from typical symptoms of anxiety and depression, investigators may be unable to discriminate reliably the active drug from placebo. We would predict that in such cases, there may be a lesser magnitude of differences between drug and placebo in therapeutic effect than is observed in trials where active drug and placebo are more readily discriminated. Our investigation is not intended to call into question the validity of the large volume of controlled clinical research that has used the double-blind procedure, but it is intended to strike a cautionary note about the scientific rigor of such research and its presumed superiority to "mere" clinical observations.

Book Forum

Nancy C. Andreasen, M.D., Ph.D., Editor

The books for this month are a holiday gift list:
books to broaden the library and the mind,
to provide pleasure and enjoyment,
to give to oneself and others.

EDITORS' NOTE: Borrowing a note from the Spirit of Christmas Past, we once again devote a portion of the holiday issue of the Book Forum to reviews of psychiatric classics. We hope that they will help to save our readers from that treacherous forgetfulness that dooms us to repeat the past.

J.C.N.

The Varieties of Religious Experience: A Study in Human Nature, by William James. London, Longman, Green and Co., 1902.

A dozen years have now passed since the publication of Professor James's monumental two-volume *Principles of Psychology* (1), which introduced many of us to the phenomena of dissociation and subconscious mental processes. His review of the psychological investigation of hysterical patients by Pierre Janet and Alfred Binet in France, and of the experimental study of hypnosis and automatic writing in England by Edmund Gurney and Frederic W.H. Myers, opened up to American readers new avenues to the psychological understanding and treatment of pathological conditions such as fugue states and multiple personality disorders. In his subsequent Lowell Lectures on "Exceptional Mental States," which were delivered in 1896 but have not as yet been published, James expanded the perimeter of the subconscious mind beyond pathogenic processes to include a consideration of the subconscious origins of the phenomena of spiritualism, demon possession, witchcraft, and artistic and scientific creativity. In this broadening of the concept of the subconscious, James has been significantly influenced by the writings of Myers, who, in a series of long chapters published in the *Proceedings of the Society for Psychical Research* between 1891 and 1895 (2), had similarly defined and described what he called the "subliminal consciousness," a term that James used throughout his lectures synonymously with the word "subconscious."

As James now turns to a study of the variety of religious experiences, he enters mostly uncharted waters. A few investigators (3, 4), it is true, have published psychological studies of conversion and mysticism, and James has also had access to the large collection of autobiographical accounts of religious experiences on which Starbuck (4) based his monograph, but James's approach to the subject is thoroughly his own, marked by scientific candor and open-minded empiricism. For James, facts speak louder than theories, and a goodly proportion of his pages is taken up with the accounts by saints and sinners of religious states they have experienced through the

ages—self-reports that graphically define the terms "religious" and "mystical."

James's empirical approach is vitally necessary for an understanding of the phenomena he has chosen to study. The subjects who speak to us from these pages describe perceptions of a spiritual world that they find profoundly moving and convincingly real—states of conscious awareness that most of us have not experienced for ourselves. Indeed, James reports of himself that "my own constitution shuts me out from their enjoyment almost entirely, and I can speak of them only at second hand" (p. 370), although it should be noted that elsewhere (p. 378), despite this disclaimer, he describes having himself once had strikingly noetic mystical states of awareness in association with inhaling nitrous oxide. While most of us, therefore, will not have personally experienced any profound spiritual revelations, we may legitimately hope, under James's guidance and from a careful study of the autobiographical material he furnishes us, to *learn about* the psychological characteristics of religious states and to perceive them in their relation to other elements of psychic functioning.

Perhaps the foremost fact that the introspective reports of religious experiences reveal to us is, in James's words, "that our normal waking consciousness, rational consciousness as we call it, is but one special type of consciousness, whilst all about it . . . there lie potential forms of consciousness entirely different" (p. 378). The ordinary rational state of consciousness with which we live and operate in our practical, everyday lives is so universal and common that it seems to many people, if not the majority, to be the only worthwhile and valid state of being. At the same time, as James cogently demonstrates throughout this volume, there is a significant minority who experience occasional states of awareness of contact with a spiritual universe of being that is as real and meaningful to them as their awareness of the external world revealed to them through their senses.

Despite, however, the similarity of the noetic conviction of the reality of its contents that is common to the rational consciousness on the one hand and the religious consciousness on the other, there are significant and important differences between them. The content and imagery of rational consciousness are derived from the sensory perceptions of the external world of material objects and result from turning one's attention outward, beyond oneself. Religious consciousness, on the other hand, is an inwardly directed, nonrational, nonsensory, intuitive, and emotional awareness and perception of a non-material but vividly real presence distinct from the self. Furthermore, whereas rational consciousness can be voluntarily evoked and set in operation by focusing one's attention on sensory perceptions and actively directing the processes of logical thought and problem solving, religious consciousness,

Clearly, he has listened carefully to the speech of many patients with schizophrenia and considered how the disruptions in their ability to communicate may reflect important and basic changes in their thoughts and emotions. This has led him to identify loosening of associations as the most characteristic feature of the disorder.

Bleuler's important work contains many major contributions. First, he distinguishes the difference between fundamental and accessory symptoms. The fundamental symptoms are those which may be considered characteristic or pathognomonic of schizophrenia, while the accessory symptoms may occur in many other types of illnesses:

Certain symptoms of schizophrenia are present in every case and at every period of the illness even though, as with every other disease symptom, they must have attained a certain degree of intensity before they can be recognized with any certainty . . . For example, the peculiar association disturbance is always present, but not each and every aspect of it . . . Besides the specific, permanent or fundamental symptoms, we can find a host of other, more accessory manifestations such as delusions, hallucinations or catatonic symptoms. These may be completely lacking during certain periods, or even throughout the entire course of the disease; at other times, they alone may permanently determine the clinical picture. As far as we know, the fundamental symptoms are characteristic of schizophrenia, while the accessory symptoms may appear in other types of illness. (p. 13)

Second, in addition to making this important distinction between specific and nonspecific symptoms of schizophrenia, Bleuler has provided us with a comprehensive description of the fundamental symptoms that are characteristic of schizophrenia. These include altered simple functions, which, in addition to associative loosening, are affectivity and ambivalence. The fundamental symptoms involving compound functions include autism, attention, avolition, activity and behavior, and intellectual decline, which is probably a secondary manifestation of the other fundamental symptoms. Bleuler also provides us with a comprehensive description of various accessory symptoms, such as hallucinations, delusions, catatonic symptoms, and disturbances in memory (which are non-specific to schizophrenia).

Third, in addition to identifying which symptoms are specific and which nonspecific in schizophrenia, Bleuler has also given us a theoretical structure with which to understand the various symptoms, subdividing them into those which are primary and those which are secondary. Using the analogy of osteomalacia, he points out that the chemical and physiological processes leading to decalcification are primary and constitute the disease process, while the fragility of the bones and a tendency toward fracture is a secondary manifestation: "The primary symptoms are the necessary partial phenomena of a disease; the secondary symptoms may be absent, at least potentially, or they may change without the disease process having to change at the same time" (p. 349). Bleuler notes that we do not know with certainty what the primary symptoms of schizophrenic cerebral disease are, although he suspects that they may reside heavily in a disruption of the pathways of association and inhibition that have been established by experience.

These observations have led him to make a fourth major contribution, the renaming of dementia praecox with the word "schizophrenia," which more clearly describes the fun-

damental and primary symptoms of the disorder. These represent a fragmenting or splitting of the associative pathways within the mind (schizo = split, phenos = mind). In this context, Bleuler notes that the term "dementia praecox" is a misnomer because not all cases decline into dementia, nor do all have an onset in adolescence; Professor Kraepelin, who proposed the use of term "dementia praecox," concurs with Bleuler that there are exceptions to the characteristic typical course suggested by the name he chose. Professor Bleuler, on the other hand, also concurs with Kraepelin that patients with schizophrenia do not ordinarily have a full *restituto ad integrum*.

Bleuler's theory of the process that produces schizophrenia assumes a biological basis that is released by psychological precipitants:

Complete justice to all these factors can only be done by a concept of the disease which assumes the presence of (anatomical or chemical) disturbances of the brain: the course of the cerebral disorder is chronic, for the most part, but there are also phases of acute forward thrusts or of standstill; the disturbance of the brain determines the primary symptoms . . . As a psychic process, the disease generally, if not always, begins surreptitiously. To start with, it remains latent until an acute pathological thrust produces prominent symptoms, or until a psychic shock intensifies the secondary symptoms. (p. 463)

Bleuler notes that a long latent period may occur between the actual onset of the disease and the first manifest symptoms. In combining biological with psychological explanations for the causes and precipitants of schizophrenic symptoms, Bleuler has provided us with a framework in which we can understand both its complex causology and its complex course.

A consensus is emerging in American psychiatry that the humanely moderate ideas of Bleuler (perhaps shaped by the pluralistic, pacifistic, and democratic Swiss environment) will prevail during the last half of this century. We have learned from the past 50 years the dangers of oversimplifying, stereotyping, categorizing, or arrogantly assuming that we can predict a particular individual's experience based on our observations (misperceived or accurate) of generic group behavior, be it ethnic, nationalistic, or illness-related. In giving us the concepts of schizophrenia and the group of schizophrenias, Bleuler has given us an approach for seeing each patient as an individual person. He has instructed us to listen, feel, observe, think, and care—with appropriate recognition of our vast ignorance, as well as our modest wisdom and capacity to understand and to treat.

N.C.A.

The Ego and the Id (1923), by Sigmund Freud; translated by Joan Riviere. London, Hogarth Press and the Institute of Psychoanalysis, 1927.

The Ego and the Id was published in April of 1923. It was the culmination of what is known as Freud's metapsychological period. The slim volume introduced to the world Freud's tripartite structure of the psyche: the Ego, the Superego, and the Id. Philosophers had for centuries puzzled over the mystery of self-consciousness/consciousness of self. The Freudian trinity provided a map to the unknown regions of otherness

within the self that anyone could follow. Freud had deconstructed the self. Unfortunately, this reified explanation of mind, which solved no mystery, became the defining moment in Freud's work. Even in psychiatric circles, the Ego, the Superego, and the Id were synonymous with Freud.

The serious reader of Freud eventually discovers that there can be no definitive reading of his complicated tapestry of texts. Freud's genius flowed in many directions and was never forced through the strait gates of either/or consistency. Some of his critics, past and present, are like lawyers who want to put Freud on the witness stand and force him to answer only yes or no. Nothing gives a more distorted view of Freud's inventive and dialectic conception of the human condition. Consider how much ink has been spilled recently over Freud's supposedly "bad-faith" shift from actual sexual trauma to the imagined trauma of oedipal fantasy in the etiology of neurosis. Freud's emphasis certainly shifted, but he never denied the importance of actual sexual trauma. To hold Freud to this either/or consistency both misrepresents his theory and ignores the fact that it was Freud who made it possible for psychiatry to speak about the forbidden subject of sexual abuse, real or imagined.

Freud wrote over several decades, and he rarely looked back. Even when he did synthesize, as in *The Ego and the Id*, it was not so much an effort to reorganize his past ideas as to move on to the solution of new clinical problems. Thus, the tripartite structure provided a formula for distinguishing among schizophrenia, depression, and neurosis in Freud's subsequent papers. That application had profound influence on American psychiatry's diagnostic nosology until the dramatic departures of *DSM-III*.

The metapsychological years, of which *The Ego and the Id* is part, was a time when Freud went beyond his clinical and empirical data to build a theoretical and even speculative structure for psychoanalysis. Lacan, the great French psychoanalyst, in his cryptic but informative fashion disparaged these efforts. For him this is the "bad Freud" who made psychoanalysis into a mere "psychology." But even Freud's inner circle was skeptical about some of these writings. Helena Deutsch, years before Lacan, was critical of what she thought was Freud's departure from empiricism. The entire orthodox American school, led by Hartmann, Kris, and Lowenstein, rejected the "death instinct" and the quasi-philosophical speculations of "Beyond the Pleasure Principle" (1).

Still, if the metapsychological era was a time of abstract theorizing and off-the-wall speculation, it seemed to have gained for Freud a better clinical understanding of depression, narcissism, masochism, and paranoia. It is difficult to imagine anyone who claims a psychodynamic perspective doing without the clinical insights of these clinical-theoretical papers.

Looking back at the end of the twentieth century, I think *The Ego and the Id* must still be considered Freud's signature piece. Freud himself described this monograph as a synthesis of ideas growing out of "Beyond the Pleasure Principle." In fact, it seems to integrate ideas from all of his papers of that era and from his earliest conception of mind in the "Project." Nonetheless, the book is an unfortunate oversimplification of the great man's supple and encompassing intuitions about the particular and the universal in human nature.

Freud, despite the growing number of his disparaging critics, has met every test of a fulfilled genius. He wrote prolifically, unlike Wittgenstein; he reached a mass audience, unlike Sartre; and he kept building on his own ideas, unlike Bertrand Russell. But, despite his pretensions and those of his followers, Freud was no more a scientist than was Karl Marx. Freud reveals himself in the brief preface to *The Ego and the Id*.

Explaining the fact that he has not acknowledged the work of others in this monograph, Freud writes,

If psychoanalysis has not hitherto shown its appreciation of certain things this has never been because it overlooked their achievement or sought to deny their importance, but because it followed a particular path, which had not yet led so far. And finally when it has reached them things have a different look to it from what they have to others.

The rhetoric is vintage Freud; he used the same analogy of a mountain walk that leads to a special view in the *The Interpretation of Dreams* (2). But what he describes is not the collective enterprise of science built on the shoulders of those who went before. This is Freud, the self-confessed "conquistador" advancing the human project of self-understanding more than any other person in this century—but with the unique vision of the artist and not through the methods of science.

The Ego and the Id is if anything pseudo-science. It begins with a theme that often troubled Freud, namely, the philosophical objections to the existence of an unconscious. Freud gives his readers a few fancy philosophical arguments of his own, which he relegates to a marvelous footnote. Responding to critics who rejected the conscious, preconscious, and unconscious as only so many "gradations in intensity or clarity," Freud comes up with a *reductio ad absurdum*. He says of authors who make analogous statements, "There are varying degrees of vitality, therefore there is no such thing as death." Such statements may in a certain way have a meaning, but for practical purposes they are worthless." Freud pointed out "how this could be seen when one tried to draw a particular conclusion, 'Therefore all organisms are immortal!'"

Although he is good at it, such logic chopping is not Freud's forte. The real point was repression, the acknowledged cornerstone of Freud's theory, which explained how critical experiences were forced into the unconscious. But even as he tells his reader, "the property of being conscious or not is the last resort, our one beacon light into the darkness of depth psychology," Freud charts a course without it in the *Ego and the Id*.

Freud's first description of the conscious, preconscious, and unconscious had been drawn from immediate human experience—dreams, jokes, parapraxias, and neurotic symptoms. Here Freud instead divides the mind into hypothetical structures with particular functions: an Ego a Superego, and an Id. The latter term he took from Groddeck, who as Freud notes followed Nietzsche. He described the relation between the Ego and the Id as like the rider and his horse, an image much like Plato's centaur. More dialectical or more paradoxical than Plato, Freud took obvious pleasure in emphasizing that the highest values of humanity, along with the basest passions, came from the Id. This seems to me one of Freud's most penetrating and most neglected intuitions. The awesome power of human faith is as obscure as human desire.

If Freud's tripartite structure seems like pseudo-science today, James Strachey, Joan Riviere, and others who presided over the translation of his works into English must take some of the responsibility. As Bettelheim and others have pointed out, Freud's German was vivid and direct. The "I" and the "It" would certainly have sounded a different note than the Ego and the Id.

Chapter three of this monograph, "The Ego and the Superego," is the launching pad for modern object relations theory. Freud posits that "identification is the sole condition under which the id can give up its objects." Character is therefore

"a precipitate of abandoned object cathexes" and "contains the history of those object choices." Nothing has troubled psychiatry more than the attempt to catalog "character." However, Freud's notion suggests that all such catalogs, including his own, are beside the point. The possibility that each person's character is in some measure a record of his or her important human encounters is both profound and believable. Particularly relevant today is Freud's speculation that what was even then called "multiple personality" was the result of "different identifications seizing hold of consciousness in turn."

Along with these extraordinary speculations, Freud gives us the quantitative mumbo-jumbo of object cathexis and ego cathexis, which is even further complicated by a new theory of instinct fusion and defusion. The latter he derived from the dualism of Eros against Thanatos as set out in "Beyond the Pleasure Principle." The nineteenth-century energetic concepts in Freud have posed serious problems for twentieth-century exegetes of his work. They seem to explain everything and they therefore explain nothing. Unlike the other ideas of Freud, they constitute an impediment rather than a point of departure for contemporary understanding of the phenomena to which Freud applied them. For example, the quantity of mental energy involved explained for Freud the difference between a recurring fantasy and a delusion, or a memory and a hallucination.

The development of the energetic concepts and the distribution of quantities of energy among the Ego, Id, and Superego became a central preoccupation of the American school. Neutralized, sublimated, de-aggressivized, de-sexualized energy were incantatory terms along with "autonomous" ego functions. These concepts gradually eroded Freud's unforgiving portrait of the inherent conflicts imposed by civilization on the human savage, replacing it with a more domesticated and adaptive humankind.

If Freud's energetic concepts became a swamp for those who tried to struggle through them, his aforementioned ideas about object loss and identification presented a remarkable challenge to the Oedipus complex, the core of psychoanalysis. Most of Freud's serious readers have recognized that the female Oedipus complex was confused and confusing. Freudian feminists, Lacan, and the Kleinians have all had a go at clarifying it. But in *The Ego and the Id* Freud threw a conceptual monkey wrench into the male Oedipus complex. If the boy had to give up his erotic attachment to his mother, then according to the premise of object loss/identification the result of the Oedipus complex should be an identification with the mother, not the father. Freud, to overcome this obstacle, posits a primary identification with the father. His argument is by no means clear and it is further complicated by his insistence on the importance of bisexuality. If anything, the Oedipus complex is remystified in *The Ego and the Id*, but in its convoluted ambiguity it may reveal more about the deeper truth of gender roles and sexual object choice than in its supposed clarity.

The last chapter of the slim volume portrays "The Dependent Relationship of the Ego." It is Freud at his most brilliant and at the same time demonstrates why William James described him as a man of "fixed ideas." (The twenty-first century may yet decide that James was Freud's equal.) Freud posits three kinds of anxiety caused by the Ego's three masters: the external world, the Id, and the Superego. This would also provide the structural formula for distinguishing among psychosis, neurosis, and depression.

Paranthetically, Freud attacks the basic existential postulate—the fear of death. He insists that "to psychoanalysis . . .

death is an abstract concept with a negative content for which no conscious correlative can be found." Freud finds it "possible to regard the fear of death, like the fear of conscience, as the development of the fear of castration." The master was so bent on explaining the present by the past that he could not imagine that humanity's greatest anxiety would come from contemplation of its uncertain future.

BIOGRAPHY

Truman, by David McCullough. New York, Simon and Schuster, 1992, 1,117 pp., \$30.00.

Harry Truman believed the White House was haunted. He wrote Bess, "I sit here in this old house and . . . listen to the ghosts walk up and down the hallway. The floors pop and the drapes move back and forth—I can just imagine old Andy and Teddy having an argument over Franklin." Once he was awakened by knocks on his bedroom door. He jumped up and put on his bathrobe, opened the door, and no one was there. "Damn place is haunted sure as shootin'," he wrote Bess.

Indeed, strange things were happening, and not just in Truman's imagination. Margaret's piano fell through the floor. Harry was told that if he sat on the presidential toilet it might fall through the floor. In truth, after nearly 150 years of neglect, the White House was about to collapse. An architect claimed he could prove mathematically that it was impossible for the house to stand.

The renovation cost six million dollars. The inside was gutted, leaving the sandstone walls standing. Under the loving supervision of Truman—historian and amateur architect—the old house was restored to resemble as closely as possible the original.

There was one addition, which hardly anyone knew about: a million-dollar bomb shelter. The military insisted on it. Truman said he would not leave Washington if there was a nuclear war, and at that time—1951—there was a "limited" war in Korea, the Soviets had the atom bomb, and a third world war was feared.

The shelter had Army cots, K rations, books, and acetylene torches to cut through the steel door if the occupants were trapped. It lacked only one necessity from Truman's standpoint: bourbon.

He had a shot of Old Grandad every morning to "get the engine going." He sipped bourbon while watching his inaugural parade, having won the 1948 election in the greatest political upset in American history. At another time, someone saw him drink five bourbons in a row, and he showed no effect. It was probably unusual for him to drink so much. In the more than 1,000 pages of this wonderful biography, he is reported to have been intoxicated only once. He was not even close to alcoholic, although he had a reputation as a drinker.

("You whiskeyguzzling, pokerplaying old buzzard," one voter wrote in an otherwise friendly letter.)

He could not have possibly drank a lot and been up at 5:00 every morning, walk for miles, work as hard as he did, maintain the remarkable physical stamina that he had, or look so young and healthy. When he became vice-president at age 60, he looked many years younger than the 62-year-old Roosevelt. Even during his retirement—which lasted 20 years—he impressed people with his youthful appearance, his bounce, his good color, the bright eyes behind the thick glasses, his good cheer, and his vitality. "Jaunty" was the word most often applied to him. He lived for 88 years and never had a serious illness until near the end. It would be imprudent to say bourbon was good for him, but apparently it did not do much harm.

This is not to suggest that drinking plays much of a role in this huge biography; it is barely mentioned. It is mentioned now because reputations are hard to shake, and this one needs to be put away. This book undoubtedly is Truman's definitive biography. It took 10 years to write, perusal of thousands of documents and letters (nearly 2,000 letters to Bess Truman alone), hundreds of interviews, long stays in Independence, Mo., and trips abroad to trace Truman's World War I experiences.

A farm boy with a high school degree, Harry Truman was an authentic hero in World War I. As captain of an artillery battery consisting of Kansas Citians, he became a hero to his men. When the war was over they kept up their friendship, became Harry's best customers when he opened a haberdashery (which failed), and promoted his career as a politician, first as county administrator and then as senator. (A man named Pendergast also helped Truman's political career; Pendergast considered Truman his honest protégé—perhaps his only one.) As long as they lived, the men in Truman's battery remained his friends. They came to Washington for his inauguration and breakfasted with Harry; he warned them not to get drunk until after the parade.

No brief review can do justice to Truman's extraordinary life and accomplishments; buy and read the book so that when it wins the National Book Award and the Pulitzer Prize, you can say you were not surprised. Here are some high points:

World War II had hardly ended before the Cold War started, with a very inexperienced Truman at the helm of the most powerful nation in the world. In rapid order came the American response to the Russian threat: the Marshall Plan, NATO, the Berlin air lift, the Korean conflict. Truman's popularity plummeted as more and more lives were lost in Korea, and firing General MacArthur led to threats of impeachment. However, when the Cold War finally ended after 45 years—without the nuclear war MacArthur and others had promoted so ardently—Truman's actions seemed eminently sensible.

Truman was a late starter. For 11 years, when others went to college or started a career, he farmed. He married his childhood sweetheart at age 35; became a U.S. Senator at age 50. He may have been a virgin when he married Bess; neither the prostitutes on 12th Street in Kansas City nor the lures of Paris seemed to undermine his Baptist scruples. Once married, Bess blushing asked the maid for new slats for the marital bed to replace several that were broken.

Truman made mistakes, and they are recorded faithfully in this book. There were scandals, but they were trivial compared with those of later administrations. Friends like Dean Acheson and Winston Churchill could not say enough admiring things about him (Churchill said he saved civilization). Even his foes, on occasion, spoke of his remarkable character, his decency, honesty, courage, and strength. He was often called the "little

man," but inside the little man—as one opponent conceded—was a blade of steel.

DONALD W. GOODWIN, M.D.

Nora: The Real Life of Molly Bloom, by Brenda Maddox.
Boston, Houghton Mifflin, 1988, 368 pp., \$24.95.

Psychiatrists have long had ample reason to be fascinated by the life and work of James Joyce. His fiction explores vast reaches of the conscious and unconscious human mind, his own personality traits and struggles against adversity were remarkable, and his daughter Lucia's schizophrenia brought him into direct contact with the world of chronic mental illness. Now, with Brenda Maddox's scholarly and highly readable biography of Joyce's wife, Nora Barnacle Joyce, we have an opportunity to appreciate another Joyce and her contributions to her husband's work, while gaining a new perspective on this unusual family. For those who have read Richard Ellmann's biography *James Joyce* (1), Nora offers an excellent complement. For those who have not, it provides a fitting introduction.

Maddox begins with the thesis that Nora has been misunderstood by Joyce's critics and that her essential role in his creations has been slighted. After we read *Nora*, our view of her as the wife who "looked after" James Joyce and the woman who served as the chief model for Molly Bloom in *Ulysses* (both, of course, notable achievements) is considerably expanded.

Maddox follows an orthodox, chronological approach in telling Nora's life story. We learn of her origins in Galway, in the rural, provincial, "truly Irish" west of Ireland, her brief formal education, and early romances. She was determined to escape the strictures of her society when she moved to Dublin and took a job as a maid (at Finn's Hotel). Nora was a striking, red-haired young woman, who cut such a figure that a stranger, the nearsighted James Joyce, hailed her on the street in June 1904. They went out on a date (probably on June 16th, Bloomsday). Less than 4 months later, she eloped with him to the Continent. Maddox portrays Nora and James's difficulties—frequent moves, money trouble, the birth of two children within 3 years—clearly. We see how Nora adapted to living abroad, learning foreign languages (she could converse in German and French but favored Italian), and living with James Joyce. Joyce's peccadilloes make an impressive list: he was extravagant with money (Nora herself was no miser), had multiple phobias, had a tendency toward paranoia, and had a virulent hatred of organized religion. Nora had to conceal her faith and did not attend Mass as long as James lived. The Joyces were not legally married until 1931.

Nora also touches on Joyce's sexual practices, which ran to the masochistic and included a "cloacal obsession." Nora appears to have responded in kind to James's erotic tastes; they exchanged scatological letters when separated. These letters are explicit enough to have aroused somewhat of a storm among Joyce scholars. Rather than recreating the controversy surrounding *Ulysses'* depiction of bodily functions, readers will be best served by remembering that the letters are part of but one phase in the marriage. The biography must, of course, show what Nora did as the "woman behind the great man," but what sets the book apart is the picture of Nora as much more than servant to genius. It is made clear that Nora and James loved each other deeply and, despite James's wandering attention, faithfully. Nora was not cowed by Joyce—she was

the only one to call him Jim and to openly criticize his drinking, and she was one of the few to plainly care about him rather than his work and fame.

Maddox cites evidence that Nora was the prime inspiration not only for Molly Bloom but also for Anna Livia Plurabelle in *Finnegans Wake*, Gretta Conroy in "The Dead" (from *Dubliners*), and Bertha in the play *Exiles*. Perhaps more impressive is the thesis that Nora's spoken and written language is Molly Bloom's, and that the cadences of her speech serve as one key to the structure and sound of *Finnegans Wake*, a book she found musical and humorous. Hearing Nora's voice in *Finnegans Wake*, where one has previously only been able to detect Lucia's thought-disordered ramblings, is refreshing.

In its portrayal of the Joyces' life, *Nora* can hold the attention of any student of family dynamics. During Joyce's period of intense writing, Nora not only had to meet the needs of this highly dependent and demanding man but to raise two children. If her triumph was her support of Joyce's work, it came at the cost of providing a normal environment for her children. Maddox shows us the pain Nora felt over Lucia's severe schizophrenia and her son Giorgio's alcoholism and inability to find any sort of useful work. She felt guilt over Lucia's illness and suffered the brunt of her spectacular rages, and Nora realized the serious nature of the disorder much sooner than James did. She did not see her daughter after 1936, although she lived until 1951. Mental illness also touched the Joyce family through Giorgio's tempestuous marriage to Helen Kastor Fleischman, which ended with Helen's institutionalization for what appears to have been psychotic mania.

Nora and James's flight from Paris during the chaotic early years of World War II, Nora's attempts to encourage James to seek care for the ulcer that killed him in early 1941, and her difficulties in the years after his death are well chronicled. For me, Nora, the individual, appears traditional and innovative during a historical period that was both orthodox and revolutionary.

All in all, Brenda Maddox makes a strong case for Nora as a person worthy of respect and attention. We learn of her humor, her respect (not always acknowledged in the Joyce community) for her husband's genius, and even her ordinariness, her straightforward nature. Joyce acknowledged her as his prime inspiration, and, in his years of exile, as a "portable Ireland." In Maddox's words,

Joyce became a man in the hands of the woman who anchored him to the featherbed reality of married love, and who opened his eyes to a new artistic vision: that the most important thing in life is love That the ordinary is extraordinary is the meaning of Joyce. Nora was ordinary. That is to say, she accepted life, with its madness, drunkenness, poverty; its music, its comedy, and its sexual imperatives. Her tragedy was that Joyce never seemed to notice that their family life and her sexual appetite, which he so admired, were sacrificed on the altar of his art In every book except *A Portrait* the last words are spoken by a woman, the Nora character. (p. 380)

Nora has something for everyone interested in the complex interplay of disease and creativity, in family patterns of illnesses such as alcoholism and schizophrenia, and in the transforming power of human relationships. We come away convinced that Joyce without Nora would likely have been a pale, overly cerebral writer rather than a true celebrant of all that is human.

WILLIAM G. RYAN, M.D.
Birmingham, Ala.

Freud and Moses: The Long Journey Home, by Emanuel Rice, M.D. Albany, State University of New York Press, 1990, 250 pp., \$59.50; \$19.95 (paper).

It was almost 100 years ago that Freud began expostulating a series of hypotheses, beginning with the study of hysteria, dreams, parapraxes, and psychosexual development, that led to the establishment of psychoanalysis. The fundamental psychoanalytic theories of the unconscious, psychic determinism, and the theory of the libido were soon expanded from the analysis of individual patients to a new and exciting explanation for the most complex historical processes and cultural phenomena. Psychoanalysis was presented as a comprehensive theory of the "mind" and human behavior, and it has been a major influence for some period of time for psychiatry and psychology. This influence became particularly strong in the United States from 1910 through 1965.

With the waning of psychoanalysis and the rise of a more scientific psychiatry as well as a psychology based on diverse schools of personality theory, Freud's charisma has faded and his heroic nature have suffered in the eyes of many. However, Freud remains a major influence in academic circles that adhere to a Freudian world view that includes history, literary criticism, philosophy, and other humane (in the French sense) sciences.

Since the opening of the Freud Archives at the Library of Congress in 1980 as well as the papers of the Freud Museum in London, a number of outstanding studies of the life of Freud have shown his weaknesses in a new light. Examples include his superstitious nature, questionable medical practices with Fliess, a distortion in his presentation of the few clinical cases that formed the nexus for his developing theories, and a highly selective use of the literature (medical and otherwise) to support his hypotheses. Although he claimed that psychoanalysis was a biological science, Freud's system was closed to important psychiatric, medical, and biological developments that occurred after 1900. He held onto nineteenth-century concepts of energetics and causality and developed psychoanalysis within a closed system of adherents to his doctrines.

One major aspect of Freud's life that has been grossly neglected by his many biographers as well as by family members (including daughter Anna) has been his Jewish background, both in its religious and cultural aspects. His family has always been presented as assimilated Jews. In fact, Freud created a myth of the history of his family so that they were identified as of German rather than East European origin because of the greater esteem in which German Jews were held in Austria and Germany.

With magnificent scholarship and the decipherment of key documents, Emanuel Rice presents a most convincing argument that Freud's early life with his parents, who by no means were assimilated, was closely tied to many aspects of Judaism. Rice, a practicing psychiatrist and psychoanalyst, attended the Rabbinical School of the Jewish Theological Seminary of America and has fluency in Hebrew and Yiddish. In addition, he received help from outstanding Hebrew scholars from the Seminary, who translated Hebrew inscriptions, in particular

those of Jacob Freud in his presentation of the family Bible to Freud on his 35th birthday.

Freud and Moses consists of two basic parts. The first consists of documentary evidence of Freud's exposure to Judaism and its significance in his early development. The second part discusses Freud's return to Judaism after an alleged lifetime of scientific atheism. In the first section, Rice's central themes are supported with exciting and revealing documentary evidence of which Freud's major biographers (Jones, Clark, and Gay) have been completely oblivious. These themes include the following: 1) Freud's parents, Jacob and Amalia, come from a strictly Orthodox Jewish background, contrary to the general opinion, and they retained many of the traditional Jewish religious practices throughout their lives. 2) Jacob Freud was a Hebrew scholar who attended a Talmudical academy in his youth. 3) Freud's parents were not adherents of the Jewish Reform movement, nor were they assimilated Jews. 4) Sigmund Freud had a traditional upbringing, which he disguised in many ways throughout his early adolescence. He learned to read through the text of the family Bible as taught to him by his father and was fluent in Yiddish and Hebrew, at least in the early part of his life. 5) Freud and his immediate family disguised and rejected their Jewishness and religious background, creating a facade of a long-term assimilated status. Freud avoided the blatant issues of anti-Semitism in Vienna during his lifetime, and these issues are not discussed in any of the published notes of the Vienna Psychoanalytic Society. After his break with Breuer in 1895, Freud also rejected any identification with the Jewish community of Vienna. Breuer was an important member of this segment of Viennese life and their most outstanding physician.

The second part of the work is an expanded analysis of Freud's late and most controversial work, "Moses and Monotheism: Three Essays." Rice approaches these essays using the methods of psychoanalysis for further understanding of Freud's relationship with his father as reflected in Freud's concept of the "primal horde." This presentation merits discussion beyond this review, but its clarity and ingenuity stimulate a wealth of controversial ideas, such as the question of ontogenesis as a reflection and in turn a model for phylogenesis. In a sense, with this work Freud returned to his Jewish roots, but how psychologically internal were the determinants for this process in contrast to the national calamities of flagrant anti-Semitism in the Germanic nations after World War I?

Freud and Moses is highly recommended to all of those interested in psychoanalytic lore and to students of the life and work of Freud.

GARFIELD TOURNEY, M.D.
Jackson, Miss.

Wilhelm II and the Germans: A Study in Leadership, by Thomas A. Kohut. New York, Oxford University Press, 1991, 320 pp., \$35.00.

In 1909 the German people were warned that "the Kaiser, about whom you are in an uproar, is your mirror image." After Germany's defeat in World War I, the minister of reconstruction, Walther Rathenau (a Jewish industrialist, soon to be assassinated), wrote that "never before had a symbolic individual [Kaiser Wilhelm II] been so completely reflected in an epoch, an epoch in an individual." Such observations about the dynamics of leadership are important; Leo Tolstoy, writing about Napoleon in *War and Peace*, raised similar questions. Do leaders determine the course of history, or are his-

torical forces responsible for bringing leaders into prominence? Now historian Thomas Kohut addresses this problem in a book about Kaiser Wilhelm II, based on his doctoral dissertation completed some 15 years ago. Drawing on his father's self psychology, Thomas Kohut characterizes Wilhelm II as a narcissistic personality, fragmented, insecure, doubt-ridden, arrogant, and grandiose, on whom Germany, a nation only recently united, projected its craving for international recognition and military power.

Born in 1859 to an English mother (Queen Victoria's daughter) and a German father (Crown Prince Friedrich of Prussia), Wilhelm sustained severe perinatal injuries: prolonged cerebral anoxia resulting in chronic hyperactivity as well as a permanently crippled left arm, which interfered with his ability to feed and dress himself and contributed to his impaired sense of self. His mother, feeling guilty and ashamed about her handicapped child, alternately overprotected and rejected him. "The idea of him remaining a cripple haunts me," she wrote to Queen Victoria, "I long to have a child with everything perfect." British and German physicians competed in attempts to rehabilitate young Wilhelm. Finally, his education was put in the hands of a stern Calvinist tutor, described by Kohut as "austere, bitter, and depressive." This man, as we see from his own description, taught Wilhelm how to ride:

Using a moral authority over [my] pupil that by now had become absolute, [I] set the weeping prince on his horse, without stirrups, and compelled him to go through the various paces. He fell off continually: every time, despite his prayers and tears, he was lifted up and set upon its back again. After weeks of torture, the difficult task was accomplished: he had got his balance. (p. 43)

Indeed, the unhappy child became an enthusiastic equestrian, loved riding in parades, and often went hunting in the royal preserves, where his servants made sure there was always plenty of game. Wilhelm's father was an ineffectual leader, overly submissive to his English wife, out of step with the prevailing mood of German patriotism, and according to Kohut an inadequate model of masculinity for his conflicted son. At age 22 Wilhelm married a German woman who was temperamentally the exact opposite of his mother, and after succeeding his father (who died of throat cancer after a brief rule) he came to depend on a coterie of male advisors who flattered, protected, and tried unsuccessfully to control him. For many years his "most intimate friendship" was with Count Philipp Eulenburg, whose homosexuality, when finally made public, led to a humiliating court scandal. Wilhelm's major political achievement, and a source of enormous pride to the Germans, was in building a huge and powerful Navy. Although it made the Kaiser seem heroic, this naval buildup intensified Germany's rivalry with England, which the Kaiser took extremely personally because of his mixed parentage. Highly sensitive to public opinion and rather lazy, he often based his policy decisions on what was printed in newspapers rather than the official documents prepared by his ministers. He ignored the advice of Germany's brilliant chancellor Otto von Bismarck, dismissed him in 1890, meddled ceaselessly in foreign affairs, and repeatedly tried to manipulate his blood relatives, namely, his cousin Tsar Nicholas of Russia and his uncle King Edward VII of England. Kohut believes that "in playing out the unresolved problems of his innermost being the Kaiser contributed to the deterioration of Anglo-German relations before the First World War" (p. 222).

Although psychiatrists can profit from reading the first part

of this book about the personal development of Kaiser Wilhelm II, the second part is difficult for anyone not thoroughly familiar with German history. Kohut gives insufficient information about political and international events to make these comprehensible for nonhistorians: the Boer War, the Samoan crisis, the Bismarck conflict, the Kruger telegram, the Moroccan crisis, "encirclement of the Reich," etc. The book is neither a biography nor a historical narrative. Ending in 1912, it leaves untold the last 29 years of the life of Wilhelm II, including the disastrous World War I, his defeat and abdication, his exile in Holland, his death in 1941, and the fate of his children. Instead, readers are given 70 pages of densely referenced footnotes.

Publication of Kohut's "study in leadership" is symptomatic of the dilemma facing psychobiographers and psychohistorians who commit themselves to exhaustive interdisciplinary research. How much and what kind of evidence is needed to make the causal connections between individuals and their social milieu seem plausible? Are psychodynamic formulations sufficient? Kohut uses them repetitively and somewhat dogmatically, but he rightly reminds us that human behavior is overdetermined. We can no longer rely on linear thinking; multiple causes lead to multiple effects, which in turn become causes. Thus, in approaching patterns as complicated as what is called leadership (in politics, science, or the arts), conscientious scholars are forced to make critical decisions between brevity—Heims's synoptic view of a collection of scientists (1), for example—versus prolixity—Richardson's multivolume study of one painter (2). Clearly, such decisions involve issues of personal taste, academic support, and publication costs.

I hope that Kohut will write a sequel to this book, giving more and deeper insights into the psychology of leadership in Germany, a country only recently reunited and already plagued with extremist tendencies that evoke memories of a deplorable historical record of intolerance and aggression.

The Flight of the Mind: Virginia Woolf's Art and Manic-Depressive Illness, by Thomas C. Caramagno. Berkeley, University of California Press, 1992, 362 pp., \$30.00.

Despite husband Leonard's confidence that Virginia Woolf had "manic depression," biographers have demonstrated low interrater diagnostic reliability. Gordon (1) wrote that there "can be no pat conclusions about Virginia's illness" (p. 54), while Trombley (2) argued that until "concrete evidence is produced, it is irresponsible to speak of her as having been mad."

Although he is not the first biographer to put an argument for bipolar illness, Thomas Caramagno, a lecturer in English at the University of Nebraska, makes a convincing case. Equipped with the current definitive text on bipolar illness (3) and his own conscientious review, he documents classical hypomanic and melancholic features, providing a rich and complete description of the myriad manifestations of manic-depressive illness.

Many biographers have suggested that Virginia Woolf was mentally well for an extended period of time, particularly from 1916 to 1941, but Caramagno appends a mood chart that contradicts this idea. Caramagno abstracted and interpreted data from Quentin Bell's biography as well as from Virginia and Leonard's diaries (from 1913 to 1919, Leonard kept an almost daily chart of Virginia's mood state, sleeping and eating patterns, temperature, menstrual pattern, and other details). Over a 45-year period—from 1895 to 1941—she had episodes of psychotic mania and/or psychotic depression in 5, moderate or severe mood states in 22, and was euthymic for only 3 of those years.

Caramagno graphs and details a strong family history of mood disorders, involving both blood relatives (paternal grandfather, father, paternal cousin, all three siblings, and mother) as well as relatives by marriage.

After confidently addressing her diagnosis, Caramagno offers an "interdisciplinary study," reexamining Woolf's "madness and her fiction in the light of recent discoveries about the biological basis of manic-depressive illness." He gives short shrift to psychoanalytically preoccupied biographers who have interpreted all of Woolf's problems as emerging from developmental factors and who find readily available answers: "As usual in a Freudian landscape, family life is hell; why else would anyone fall ill?" Caramagno engages in deliciously selective quoting. He refers, for example, to Alma Bond's view that Woolf chose to become mentally ill to avoid growing up and that some of her lifelong difficulties "probably" resulted from her mother's having "devalued" her daughter's feces. He criticizes the view that Woolf's breakdowns were "neurotic guilt-driven responses" to a set of childhood traumata (early death of mother, sexual abuse by stepbrothers, subsequent deaths of brother, stepsister, and spiritually misanthropic father) as well as adult stressors (a pusillanimous husband who refused her children), both for its doctrinaire inflexibility in elevating theory over evidence and for its promotion of the model of the neurotic artist.

If psychoanalysis is to survive into the next century and stop "blundering into complex situations in search of a simplistic cause-effect relationship," Caramagno argues that there must be some convergence of the "soft" and "hard" sciences. While castigating those critics who fail to familiarize themselves with modern neuropsychiatry, he attempts to preempt accusations of biologism by stating that we must recognize "that our subjective lives are complicated mixtures of mind and brain, the freely chosen and the brutally imposed, the meaningful and the unintelligible."

So Caramagno does not reject the influence of developmental factors but, in offering a pluralistic "neurobiography," he suggests that Woolf handled those "emblematic events" adaptively in that she recognized a need to "develop an independent, confident, adaptive self." Fiction was for her a source of nurture and a creative mechanism for exploring pervasive themes—"mothering, madness, and the universal human need for a meaningful therapeutic mirroring of self-continuity in a world that can . . . inflict pain, loss and powerlessness."

While assertive in damning psychoanalytic views, Caramagno does not consider other reasons for some biographers minimizing or denying Woolf's "madness." Supporters of Woolf have defended her against the perceived demeaning stigma attached to such a term, while others have overreacted to the limitations of her treating psychiatrists, who have been portrayed (2) as afraid of Virginia Woolf—a liberal feminist who threatened their Victorian views (especially of a woman's role and of life requiring the imposition of black and white solutions).

Caramagno moves to a more difficult issue—seeking to explain how Woolf attempted both to explore her own bipolar symptoms in the characters she created and to integrate the consequences of her mental illness into her writing in the absence of any established formula for processing psychotic experience in literature. Although mania did quicken her imagination and depression cut into her creativity, she recognized the false perceptions of each, especially after the “shock of falling out of solipsistic mania.” She wrote best in a euthymic state where she could “reconnect mind and world” and balance “the unrestrained imagination with an external coherence,” seeking to capture a moment of being. Cassell (4) has described how sick people suffer a disconnection from their usual world and a loss of control over themselves and the world and has defined such dissolution of the social personality as illness. Most people seek strenuously to connect. Caramagno’s argument is, in effect, that Woolf sought to deal with the state of being disconnected, to define it and explore it, rather than strive for any one particular “meaning.” Further, he says that she exemplified the importance of tolerating uncertainty, confusion, multiplicity, and pointlessness because they represent the “real thing,” a message echoed of course by many contemporary writers and playwrights (e.g., Kundera and Stoppard). Woolf rejected the safety of order and went on to define the steps required to survive the loss of meaning.

Just as Woolf, in her writings, did not satisfy the reader’s need for narrative unity, Caramagno hints at an irony. Critics and biographers have sought and continue to seek definitive answers from her, from her writings (criticizing her, as an acknowledged analyst of human emotions, for refusing to sum up people) and from aspects of her life (criticizing her for not providing an explanatory statement about her suicide). Thus, they miss Woolf’s integral message—that indeterminacy is worth the risk because coherence, linearity, and closure can obscure. Caramagno reminds Woolf’s biographers of her message—that their psychological preconceptions reduce complexity to simplicity by eliminating the meaning of complexity. And that when “a psychological profile makes too much sense, something has been ignored.”

Caramagno proceeds to provide a revisionist literary analysis of five of Woolf’s novels, focusing on her illness and bipolar sense of identity. He suggests that having manic-depressive illness polarized her experience, with “oppositions . . . deconstructing . . . each other,” and that she then sought the task of integrating and fusing disparate experiences through her art, creating a sense of self that recognized the validity of the multiplicity of her experiences. She sought in her fiction “a marriage of [the manic and depressive] modes of perception, the ability to imagine wedded to a lucid recognition of reality, an epiphanic moment when her inner being and outer world co-operated with each other, each ratifying the existence and the worth of the other.” Caramagno argues that Woolf’s capacity to tolerate and deal with polarities (“bipolar cognition and syncretic vision”) emerged from her illness and right/left interhemispheric neuropsychological mechanisms. Such a view is plausible, but the frequent artistic preoccupation with polarities and dualities is not limited to those with bipolar illness.

Caramagno considers why so many successful artists have suffered from affective disorders. He suggests that manic-depressive artists not only have intensified sets of beliefs and insights (and self-confidence to risk self-disclosure in public) but also capture their unique or discordant subject-object boundaries and self-world transactions in their art, providing works that are alien to the reader’s customary ways of seeing the world. If, as is argued, interpretation is a function of iden-

tity, readers then have to set identity aside, accept the initial disturbance, and allow the literature to generate a new subjectivity within themselves. Once “occupied” by the thoughts of the author, new subject-object boundaries are drawn, discovering or reshaping aspects of the self. According to Caramagno, the manic-depressive artist has a greater capacity both to provide such an artistic effect and to provoke such reactions in the reader.

As Kay Jamison notes in an “afterword,” Caramagno gives us a “broad and compassionate look into Woolf’s life and work . . . combining the perspectives of modern psychiatry with his own background in literary criticism.” Lucid and scholarly, fresh and provocative, this is a superb book.

Charles Ives: “My Father’s Song”: A Psychoanalytic Biography, by Stuart Feder. New Haven, Conn., Yale University Press, 1992, 368 pp., \$35.00.

Psychobiography has, until recently, been the haunt of amateurs. Typically, we (they) are trained in one of the fields, but not in the complementary one necessary to the scholarly work (if not to the occasional insight). There is some outstanding work, such as that of Erikson and Steven Marcus, but Freud’s work on Leonardo (1) is seriously marred by his mistranslation of the primary datum, and Slater and Meyers’ understanding of Handel (2) was led astray by their reliance on secondary and tertiary sources. The problem of specialized skills is further compounded when the field of study involves specific technical knowledge, such as music.

Charles Ives, that most American of American composers, requires a biographer with just such multiple and overlapping skills, and he has found them in Stuart Feder, a psychiatrist, psychoanalyst, musician, and, above all, a scholar. Feder begins his book with a skillful evocation of mid-nineteenth century Danbury, Conn., and the generations of Iveses, a historian’s accumulation of multiple illuminating details. The composer’s father, George, despite or perhaps because of his family’s banking and merchant background, was a trained musician, a Civil War Army bandmaster, and, by the time of his early death, a failed professional musician and a failed businessman. However, he remained a hero to his son Charles. Feder gives us the details of Charles Ives’s growing up, his education at Yale, his stumbling into the insurance business, his marriage, and his physical and mental deterioration, but the focus is on Ives the composer, identified with as well as remembering and memorializing his father.

A characteristic of Ives’s music is its autobiographical reference. This takes many forms: quoted tunes, crossing sounds mimicking the “noise” of two bands playing different marches, imitations of his father’s musical and sound experi-

ments as well as the words of his songs and his comments on the manuscripts. All of these, along with Ives's own writings, are used to build a convincing argument for a continuing fantasy of continued musical collaboration with his father. What is remarkable is that this is done with a refreshing absence of psychoanalytic jargon and reference. (There is reference to only a single paper by Freud.) Similarly, Feder is also able to communicate meaningfully about the musical devices Ives used and at times invented, such as particular chords and dissonances, polytonality and polyrhythmicity, without resort to highly technical language. Although conflict clearly played a role in the nature of the musical product, the compositions transcend that portion of their origin and reach out to the universals that underlie our response to great art. Ives's music is an "aesthetic crystallization of . . . nostalgia," his own personal affectively colored remembering as well as our sense of our own personal and historical past.

Curiously, although understandable in a book intended for a broad audience, Feder does not make any psychiatric diagnoses. However, the data are presented. My own differential would include spelling disability and perhaps other learning difficulties early in life, manic-depressive disease, and postinfluenzal encephalitic organic brain disease. The lattermost may well account for Ives's increasing irritability, shaky handwriting, and other difficulties. The now undeterminable diagnoses are not central, however. More important, we are provided with a rich view of both man and composer, of mental function and mental product, and of how one led to the other by shaping the passage of sound and silence through time. *Charles Ives: "My Father's Song"* is an appropriate model for how to do psychobiography or, for that matter, biography right: use primary sources, recognize the distortions present even in primary data, be cautious in interpretation, and insist on overlapping confirming data. Ober (3) recently pointed out that each teller of a tale reshapes it to fit his or her own needs and that we must trust the tale and not the teller. Feder tells the story whole; I believe the real Ives lives in this book. It is also a delight to read, cleanly and elegantly written.

THE HUMAN EXPERIENCE

How It Feels to Fight for Your Life, by Jill Krentz. Boston, Little, Brown and Co., 1989, 144 pp., \$15.95.

This is a handsome book from an award-winning author-photographer and a distinguished publishing house. It is the result of a series of interviews with children who have or are facing serious illness.

It does not claim to be scientific. In fact, the author sought a biased sample: "I traveled around the country to find and

listen to very special kids." The intention was to produce an inspirational, instructional work. Children were sought "who were dealing with their adversity in ways that would inspire and instruct other sick kids and the adults who love and work with them."

Fourteen portraits are presented of children and adolescents aged 7-16 years with illnesses ranging from congenital heart disease requiring open heart surgery, through cancer and a host of other diseases and traumas, to childhood diabetes.

Is there anything the profession can learn from these children? Joseph Buck, Elizabeth Bonwich, and Alisha Weissman, although grateful to their doctors, find them to be somewhat uncommunicative and draw greater support from other health care professionals and other patients. Three children mention contact with psychiatrists, but only one, Spencer Gray, finds this to be beneficial. A number of the children have strong religious beliefs, but Stuart Ugelow says he "lost any hope of believing in religion . . . If there is a mighty and powerful creator who controls the world he wouldn't let things like this happen." Two are very critical of healthy people who smoke tobacco. Elizabeth Bonwich suggests that "one of the requirements for a medical degree should be to have had a serious illness."

The book is not written or intended for consumption by professional behavioral scientists. Therefore, to judge it by such standards would be unfair. Nevertheless, no account of a primary emotional disorder is offered, and this is an omission. Loss of family, incest, childhood depression, and suicide are painful experiences that could have been included. There is, however, mention of the symptoms of posttraumatic stress disorder in the account of a burned patient and a suggestion of the same in an adolescent with traumatic paraplegia.

As expected from this accomplished artist, the black and white graphics are outstanding. Severely ill children and their families need immediate, interactional relationships that address their own specific problems, so this book may not be an "inspirational" work that can stand alone. But it may help.

The value of this book is the insight it provides into the way certain children and adolescents have dealt and continue to deal successfully with massive adversity. It is an object lesson to all middle-aged adults. It has a place in all school libraries, where it will inform, encourage, and inspire healthy children.

SAXBY PRIDMORE, M.D.
Hobart, Australia

Before Their Time: Four Generations of Teenage Mothers, by Joelle Sander. New York, Harcourt Brace Jovanovich, 1991, 190 pp., \$19.95; \$9.95 (paper).

Last year, I received a Christmas present in July from Dr. Andreasen, a book to review that touched an area I was particularly interested in: ethics. This year, my gift was a book dealing with teenage pregnancy. I expected to find a dry statistical treatise, replete with a number of interesting but soon to be forgotten pages. Instead, I was a spellbound reader of the personal story of four women: 20-year-old Leticia Johnson; her 39-year-old mother, Denise Benjamin; her 63-year-old grandmother, Rena Wilson; and her 83-year-old great-grandmother, Louise Eaton.

Over a period of 4 years, these women told the story of their lives, their pregnancies, and their experiences as young mothers to Joelle Sander, a writer, researcher, and therapist. The voices of these women who became teenage mothers are amplified by an introduction written by Dr. Robert Coles, an oral

historian, who reminds us that "it is hard for us, no matter our good will, to quite fathom the circumstances of those who live at a great remove from us—their lives, their assumptions and expectations so different from ours." He is, indeed, right. Although my daily practice brings me in contact with impoverished black and white teenage mothers, this longitudinal slice of the lives of four black women made their stories much more real. Through the ebb and flow of their memories, their thoughts, and their feelings and through their voices, I learned not only about their early pregnancies but also about the struggles that have scarred their lives and the progressive emotional and moral disintegration of their families. These families, which started out as hard-working, upwardly mobile, and responsible, have steadily disintegrated because of the severe stress attendant to poverty, unemployment, and skin color. Like Dr. Coles and Ms. Sander, I was moved as I read of the experience of these families and the social and personal tragedies that these women experienced and continue to experience.

Ms. Sander takes to task our national priorities, policy, and programs. Each woman whose life is described in this book has complained about the economic, psychological, and social struggles she faced as a child and continues to face. Each has complained about the unresponsiveness of federal, state, and local governments that claim to provide aid and assistance. Ms. Sander makes recommendations that we have heard before. She first looks at the familial dynamics that led to all of these women's pregnancies—loss of a father through abandonment or death, loss of a mother through neglect or depression, and loss of a responsible peer group and the premature substitution of a male, any male, and a baby, any baby, to offset vulnerability. Ms. Sander makes recommendations with regard to services and programs that encourage young people to be sexually responsible. She makes it clear that total abstinence is not the answer; it will not work: "Although only five percent of teenage girls and 17 percent of teenage boys report having intercourse by their 15th birthday, 44 percent of girls and 64 percent of boys report being sexually active by the time they reach 18. More alarming is the fact that only 40 percent of teenagers report using contraception sometimes." Although the availability of contraception and contraceptive services is vital in protection from pregnancy, contraception is only the beginning. Young people need clear and comprehensive sex education; they need to have the options of adoption and legal abortion. Young people who choose to keep their children need services to help them cope—prenatal care, health care for themselves and their children, opportunities to finish their education (including on-site child care), psychiatric and psychological counseling, and parenting skills classes that are accessible. They also need fathers who are interested and available parents—for themselves and for their children. Ms. Sander suggests a need for a school system that stresses not only sound academic skills but work training and work opportunities, a school system that has links to industry and decent non-dead-end jobs.

For the most part, Ms. Sander's suggestions focus on outside interventions rather than psychological changes. It is clear that it is difficult, if not impossible, to effect change when one leaves for school in the morning hungry and returns from school to an empty refrigerator with no promise that there will be food tomorrow.

1990 census data from the Children's Defense Fund, a non-profit group based in Washington, D.C., documented the extraordinarily high levels of child poverty in my home town of Detroit, where 46.6% of children under the age of 18 (about 138,000 children) are in poverty, 6.7% more than in 1979,

and 52.4% of children under age 6 (about 56,450 children) are in poverty. The fact that one out of two children in Detroit lives in poverty reflects the impact on children of the disappearance of factory jobs in once-thriving automobile cities, and this is an underestimate. These children go hungry at the end of the month when food stamps run out, have limited access to health care, suffer physical and sexual abuse and neglect, drop out of school, and become teenage mothers. Abstinence is not a solution for these children; neither is simple access to contraception.

In 1989, the federal government spent \$21.5 billion to support families started by teenagers. What will they spend in 1995 and in the year 2000? Now, in the 1990s, nothing short of a national resolve is needed to significantly reduce the tragic circumstances that these four women have suffered. We must face the challenge and change national priorities. I thank Dr. Andreasen for helping me to think about the real meaning of the holiday season.

ELISSA P. BENEDEK, M.D.
Ann Arbor, Mich.

Words I Never Thought to Speak: Stories of Life in the Wake of Suicide, by Victoria Alexander. New York, Lexington Books (Macmillan), 1991, 238 pp., \$22.95.

When I arrived home one evening, I found this book waiting for me. I had plans for the evening, but as I flipped through the book, I realized that it had to be read immediately. The stories of survivors (Victoria Alexander defines "survivor" as one who has experienced the loss of someone close through suicide) are compelling. This book was conceived by a woman who experienced the loss of someone close through suicide. In her eloquent introduction, she describes the difficult process of writing her book—listening to the experience of others and writing about her own; the times she stopped the process because it was too painful.

The book is divided into four chapters. The first deals with the secrecy and silence surrounding suicide and the need for survivors to tell their stories, to find language that can communicate their feelings. Alexander describes the regions of grief and some of the concomitant feelings that survivors may have, such as relief or anger, as well as the overwhelming confusion. It is in the subsequent chapters, however, that these concepts are best described. The strength of the book lies in the personal stories.

The following chapters are loosely based on a time sequence of mourning—"At the End/At the Beginning," "The Midland," and "Then and Now." As the author points out, the book can be read in different ways—reading each chapter in any order or following one person's narrative through time. I chose the latter because I wanted the continuity of each person's storytelling.

The survivors describe the initial shock and disbelief (one woman, whose mother had threatened and/or attempted suicide at least twice a year during her lifetime, thought that her mother had been murdered when she finally "succeeded") and the minute details (a coffee cup, a look, a hand squeeze) that can take on an eerie significance in the mind of a survivor. The stories confirm the universality of some of these responses. One mother ruminates as she reanalyzes the situation, "What if I had noticed, had insisted . . ."

The stories also describe the realignment of relationships once a family member is gone (a woman who becomes the only child after her brother dies, a woman who must work on

her relationship with her lover's children after her lover dies), the anniversary rituals, and the reemergence of overwhelming feelings during holidays and other milestones.

All the individuals who have shared themselves in this book seem to have a positive outlook on their own lives, although a suicide of someone close can bring the thought of suicide closer, too. It is no longer an abstract idea.

Although the people in this book do not represent all "walks of life"—all appear at least college-educated and many have graduate degrees—the stories reveal the universality of the confusion, feelings, and healing that take place after the suicide of someone close. The stories also describe more than the experience of a suicide survivor. Anyone living with someone who has a mental illness (in many of the stories, the person who committed suicide had a history of previous attempts as well as unstable and unpredictable behavior) or anyone who has suffered a death of someone close can read these stories and find feelings and thoughts that resonate with their own. It is a book that all mental health professionals should read and be able to recommend to their colleagues and patients.

MICHELLE KIM LEFF, M.D.
Silver Spring, Md.

Stronger Than Death: When Suicide Touches Your Life, by Sue Chance. New York, W.W. Norton & Co., 1992, 176 pp., \$19.95.

The death of a child violates the natural order. Children should bury parents, not the other way around; the fear of a child's death is arguably a parent's worst nightmare. When a child dies and this death also happens to be a suicide, the aftermath may be unendurable for survivors. Depression, post-traumatic stress disorder, and psychosomatic illness commonly strike suicide survivors, clouding their lives for years. Unfortunately for some, their entire life is plagued by dysphoric symptoms. Emotionally, these survivors are among the walking wounded, unmistakably experiencing the dispirited sense of self common among those who have suffered the purposeful death of a loved one.

On November 16, 1984, Dr. Chance's son, Jim, committed suicide by gunshot. He was 25 years old and her only child; he was also bright, sensitive, and silently depressed. Disheartened about his future, he could not imagine that life still expected something of him. His self-perceived flaws proved fatal, while his mother viewed these same flaws as insignificant compared with the rest of him.

Psychiatrists may already be familiar with the author from her regularly featured column in *Psychiatric Times*. Dr. Chance's column usually addresses relationship issues in a tone that is chatty and much like a letter to friends. This new book is different. It is a tightly written, well-crafted work with sharp focus and brutal honesty. The writing style is vivid and direct. Undoubtedly, Dr. Chance loved her son, and her writing, in part, brings him back. It is remindful of the lines John Gunther wrote in *Death Be Not Proud* about his son, who died of a brain tumor: "I want to make some part of him come alive, if only in the feeble light of words" (1). The strength in *Stronger Than Death* is love: the life-giving dynamic that points to creativity, growth, and adaptivity. In the wake of tragedy, Dr. Chance's suffering shows that love can make one better, not bitter.

Years ago, I learned that recommending books to friends, colleagues, and patients is a tricky business, even when the

text is carefully selected and well-intentioned. Despite this, I know of no other book that so poignantly addresses the aftermath of a completed suicide for survivors. There seems to be scant professional or lay literature on the impact of suicide on friends and family. Victoria Alexander's *Words I Never Thought to Speak* (2), written for the popular press, comes to mind as an exception. The intent of *Stronger Than Death* is not to cite the reasons and myriad misperceptions that lead a person toward suicide, themes which are rehearsed widely in psychiatric writing. Instead, the author explores the seemingly bottomless emotional anguish endured by survivors, and she hopes to help others by sharing her pain and knowledge. She properly recognizes that although a suicide victim's blood is on that person's hands only, the act of suicide places a skeleton in other people's closets, overshadowing their lives with tears, loneliness, guilt, and obsessive rumination. The message in *Stronger Than Death* echoes Viktor Frankl's credo: "In a word, each man is questioned by life; and he can only answer to life by answering for his own life; to life he can only respond by being responsible" (3). For survivors, the therapy of recovery starts with turning to others to endure the unendurable, and slowly, with communication, the wound that feels so private begins to be understood within a greater story.

The author kept a journal for 9 months following her son's death. She shares selected passages, interspersing them throughout the book and thus enriching the text with graphic documentation of the slow and almost imperceptible pace to recovering and getting on with life.

Psychiatric writing concerning suicide concentrates almost exclusively on epidemiology, diagnoses, risk management, and prevention. In this regard, Sue Chance, as a psychiatrist, has broken new ground by writing a book that examines the grave repercussions the act of suicide unchains among the living. This book is intended for a broad audience, with specific importance for all primary care physicians, mental health professionals, those contemplating suicide, and survivors who have suffered the suicide of a friend or loved one. Yearly, an estimated 200,000 people in the United States are added to the ranks of suicide survivors, and this book offers practical treatment approaches to promote their healing.

Stronger Than Death is a plainspoken and important book for clinical psychiatrists. When next browsing in a bookstore, pick it up and glance at the first paragraph, a powerful prelude to an inspiring story.

CAPT. JOHN R. CUSACK, MC, USN
Charleston, S.C.

Child Prodigies and Exceptional Early Achievement, by John Radford. New York, Free Press, 1990, 255 pp., \$22.95.

Curly Sue, Little Man Tate, and Kevin (who gracefully vanquished the bad guys when he was left home alone) attest to the fact that this is an era of prodigious moppets. This book tills this familiar ground with diligence and, delivering even

more than its title promises, delves into the ever-fascinating relationship between exceptional capability and accomplishment. Can precocity be measured? How specific or general is it? What are the conditions that bring it about? Can it be fostered, and if so, how? To his credit, John Radford conducts a lucid and engaging tour of this tricky territory with its political and ethical minefields—territory that is strewn with the wreckage of scientific skullduggery, parental chicanery, and media hype that feeds on public credulity.

Radford's sources range widely from the professional literature to the popular press. He reviews both the classic studies of Galton, Lombroso, and their ilk and the more recent and more systematic work of Terman, Watson, Rutter, and Gardner. There are gossip and fascinating life history data on such famous prodigies as John Stuart Mill, William James Sidis, and Norbert Wiener. More journalistic accounts describe the lives of the Quiz Kids, child movie stars, feral children, and idiots savants. A broad swath of precocity and accomplishment is covered—in music, science, mathematics, literature, chess, competitive sports and games, and even spirituality and leadership. Radford also takes up the perennial concern with fostering and enhancing high accomplishment. He reminds us that concentrating special educational methods on small children to develop their intellectual potential is not solely the invention of post-Sputnik America. Such attempts go back to Ulysses, who engaged Mentor to teach and guide his son Telemachus, to James Mill, whose careful regimen fostered John Stuart Mill's sober genius, and to many other less prominent parents through the ages. We learn that Japan, the Soviet Union, and Britain have all been hospitable at one time or another to bold experiments in expanding children's capabilities.

Radford appears to be baffled by one important finding in all the studies: that youthful capability, however measured, and actual adult achievement are not closely correlated. He seems aware that something is missing in his understanding of the issue—a factor that he sometimes refers to as motivation, or the ability to apply oneself to the task. If he had read chapter 14 of *Manic-Depressive Illness* by Goodwin and Jamison (1), he might have divined a clue to the missing factor and thereby enriched the book. These authors clearly document that the manic-depressive diathesis is highly correlated with extraordinary achievement. The energy, rush of ideas, and associative exuberance of mania, when harnessed and channeled, propel talent into the orbit of high achievement. Any of us who practice within or near great universities can attest first-hand to the contribution of hypomania to creativity and intellectual accomplishment.

Child Prodigies and Exceptional Early Achievement offers the reader a lively, comprehensive survey of a thoroughly engaging field. It does so without pretending to offer new solutions to many of the familiar riddles, foremost among which is the mysterious concatenation of biological, social, and psychological conditions that have produced such individuals throughout recorded history.

THE GENERATIVE MIND

The Lopsided Ape: The Evolution of the Generative Mind, by Michael C. Corballis. New York, Oxford University Press, 1991, 351 pp., \$24.95.

Perhaps there is no more blissful state for the academic than being obsessed with a theory that is not only consuming but begins to explain everything. Whether one inflicts these obsessions on the world or keeps them as a private delight is always the problem. Dr. Corballis has chosen to share his obsession with us. What emerges is a most interesting book about the left hemisphere of the brain, its language functions, and how it has evolved over time. This is an interesting book that charts the evolutionary development, not only of language but of brain function as well.

The book begins with a major question. The first chapter is entitled, "Are Humans Unique?" This is succeeded by seven chapters, each of which can stand by itself, covering the topics of human evolution, the development of bipedalism (or the implications of learning to walk and having one's hands free), human handedness, human language, the evolution of language, language and the brain, and praxis and the left brain. Each of these chapters is an excellent review of the literature in its area, although as reviews they all have the usual problem of being too superficial for the expert and too detailed, perhaps, for the layman. In general, however, they are quite readable. Each chapter is written so that it can stand alone, and, as such, each would be a nice *Scientific American* essay.

The last three chapters, "The Generative Mind," "The Duality of the Brain," and "The Plastic Brain," are the crux of Dr. Corballis' argument, and argument it is, because very few data are presented. Basically, he postulates that there is a generative assembling device that is based on vocabulary and located in the left hemisphere. It is this ability to generate language and images that distinguishes human beings, in great part, from the rest of the animal world. He notes, "It is the basis of a discontinuity that is at least of the order of that which distinguishes animals that fly from those that do not. The proof of this is that a Generative Assembly Device (GAD) did eventually permit us to fly in airplanes, helicopters, and space capsules, and only as a particular case of a very general power that this bestows upon us" (p. 311).

His conclusions are very theoretical, but Corballis' book is a gold mine of many interesting tidbits and facts about evolution and handedness, and while it will not change anyone's research endeavors, it certainly is an extremely interesting book to read about the relationship of man to the rest of the animal kingdom. He discusses the implications of handedness and how left-handed people have been treated throughout the ages, even reporting that there is some evidence from flint tools from 150,000–200,000 years ago indicating that their makers were right-handed.

LITERATURE

A Dream of Mind: Poems, by C.K. Williams. New York, Farrar, Straus and Giroux, 1992, 100 pp., \$16.00.

"I couldn't put it down" is a phrase not often associated with a volume of poetry. This book is an exception. C.K. Wil-

liams, who won the 1988 National Book Critics Circle award, is one of the nation's most gifted poets. He writes about the themes that tend to interest psychiatrists—sex, love, jealousy, anger, aging, disease, and dying. Like many psychiatrists, he is also interested in the workings of the mind, turning his attention inward and creating a sort of poetic metapsychology of dreams, meditation, prayer, and abstractions about mental life. His genius is most striking when he observes and communicates the moment, the incident, the image of a person. For example, in "When," he describes a dying man,

he wanted out of the business, out of the miserable game, and he told whoever would listen, whenever they'd listen, wife, family, friends, that he'd do it himself but how could he, without someone to help, unable to walk as he was, get out of bed or up from the toilet himself?

In "Harm," he sees that a homeless vagrant relieves himself in the street,

and that a slender adolescent girl from down the block happened by right then, and looked, and looked away, and looked at me, and looked away again, and made me want to say to her, because I imagined what she must have felt, It's not like this, really it's not this, but she was gone, so I could think, But isn't it like this, isn't this just what it is?

In "Child Psychology," Williams speaks of latency and libido, of oedipal adventures and the return of the repressed, when

we were going somewhere and without telling him I took my father's keys and went outside to wait. House, car, office keys: how proud I was to be the keeper of that weighty, consequential mass. I stood there, tossing it from hand to hand, then, like my father, high into the air. And then I missed, and saw it fall, onto the narrow grating of a storm sewer, and then in.

In "The Cautionary" (my favorite poem in the volume), which was first published in *The Times Literary Supplement*, Williams writes about a man and his attractive, somewhat younger wife:

he decides that it's not he himself, as himself, his wife desires, but that she simply *desires*. He comes to think he's incidental to this desire, which is general, unspecific, without object, almost, in its intensity and heat, without a subject: she herself seems secondary to it, as though the real project of her throaty, heaving passion was to melt her mindlessly away.

In "Helen," Paris says of the dying Helen,

The next night her cough was worse, with a harsher texture, the spasms came more rapidly, and they'd end with a deep, complicated emptying, like the whining flattening of a bagpipe. The whole event seemed to need more labor: each cough sounded more futile than the last,

as though the effort she'd made and the time lost making it had added to the burden of illness.

Williams is introspective and self-reflective. In "She, Though," narrated by a writer, he speaks of the dedication of an artist:

That dedication, or obsession, or semblance of obsession, counted for much in those days. For most of us it was all we had, struggling through our perplexed, interminable apprenticeships. We were trying to create identities as makers and as thinkers, and that entailed so much.

When he writes about people or events, this self-awareness leads to a double consciousness of what was and of what the poet saw and felt and thought about what was. We have access to a vivid representation of the world and at the same time share a privileged participation in his personal view of it. This self-awareness works less well when it is directed only inward. A third of this book is occupied by the cycle of 16 poems providing the title for the volume. The cycle starts with "The Method":

A dream of method first, in which mind is malleable, its products as revisable as sentences, in which I'll be able to extract and then illuminate the themes of being as I never have. I'm intrigued—how not be?—but I soon realize that though so much flexibility is tempting—whole zones of consciousness wouldn't only be reflected or referred to, but embodied, as themselves.

Later, in "Vocations," he explains,

they can be considered in a way that implies consequence, what I come to call the dream's "meaning." Although I can't quite specify how this ostensible meaning differs from the sum of its states, it holds an allure, *solutions* are implied, so I keep winding the dream's filaments onto its core. The problem is that trying to make the recalcitrant segments of the dream cohere is distracting.

In "The Gap," he adds,

So often and with such cruel fascination I have dreamed the implacable void that contains dream. The space there, the silence, the scrawl of trajectories tracked, traced, and let go.

He also says, in "The Fear,"

In my dream of unspecific anxiety, nothing is what it should be, nothing acts as it should; everything shifts, shudders, won't hold still long enough for me to name or constrain it. The fear comes with no premonition, no flicker in the daily surges and currents of dream.

I read these impatiently, eager to get back to narratives with plots and characters. Williams' gift of language is immense and apparent, but without the content of real people and concrete events, his view of mind and mental life failed to hold me.

Of course, poetry is the music of language as much as the

meaning, and Williams is a virtuoso of words. His style is quite distinctive; his lines are said to be the longest of any poet writing today. This permits, or perhaps demands, that he include all of the possibilities inherent in each thought, each moment. He turns to runs of words in which the same consonant is used repeatedly when he wants to carry us with him through an image and then shifts to short, almost clipped syllables when he wants us to pause and consider. For example, in my favorite, "The Cautionary," we have "a man who's married," who broods "fretfully on her faithfulness," and observes with a "degree of detachment" until the flow is disrupted as "it dawns on him in a shocking and oddly exciting insight."

The impact of this is subliminal: one must study closely to discern how Williams achieves his effects, but the impact is nonetheless powerful. Others who attempt to use language to communicate ideas with emotional impact might well consider their use of language as carefully.

Williams deserves a wide audience. He is an important poet and a first-rate psychologist as well.

ROBERT MICHELS, M.D.
New York, N.Y.

When Nietzsche Wept: A Novel of Obsession, by Irvin D. Yalom. New York, Basic Books, 1992, 306 pp., \$20.00.

This book is an artful mixture of fiction and fact. A prominent, middle-aged, Viennese physician (Josef Breuer) goes to Venice in 1882 hoping to subdue his guilty desire for sexual intimacy with a patient he has been treating with massage and psychotherapy (Bertha Pappenheim). He meets a seductive feminist (Lou Salomé) who persuades him to treat an ex-lover suffering from migraine and "despair" (Friedrich Nietzsche). Reluctantly, Breuer agrees to meet Nietzsche in Vienna, but not before we learn about the doctor's busy life there, his devotion to patients, his world-weary depressiveness, his flirtation with his office nurse, his ambivalence toward his wife and family, his fear of death, and his self-loathing. A stabilizing influence seems to be his friendship with a young neurologist ("Sig" Freud), who enjoys taking hot baths and copious meals with Breuer's family and discussing interesting cases with him.

Nietzsche's philosophizing and reluctance to disclose any personal problems proves highly frustrating for Breuer. They engage in long dialogues about truth that seem labored and beside the point in view of Nietzsche's concern regarding whether he will become a chronic invalid. Freud suggests to Breuer that "stress" might be a causal factor in migraine and that psychotherapy could prove useful (one of several ahistorical episodes in this book—the concept of stress did not enter medical thinking until nearly three-quarters of a century later) (1). After a few nonproductive sessions, Nietzsche collapses because of a severe migraine attack and nearly dies. Breuer then decides to try an unorthodox approach. He hospitalizes the patient under an assumed name and suggests that they exchange roles. Now Nietzsche is the doctor and Breuer the patient. Breuer reveals some weird dreams (faucets dripping insects, machine parts, and odious slime), which Nietzsche tries to interpret using techniques like free association, guided imagery, and behavior therapy, but nothing helps. While strolling through a cemetery Nietzsche and Breuer come upon Breuer's family tomb, and Nietzsche notices that Breuer's mother's name was Bertha. Breuer grudgingly acknowledges that there may indeed be a future for the "talking treatment"

and for "Angst doctors" who are trained to understand what symptoms mean. His obsessive desire for Bertha suddenly becomes clear:

The more blatantly she idolized *me*, the more I imbued her with power. She was the anodyne for all my anguish. Her merest glance cured my loneliness. She gave my life purpose and significance. Her simple smile anointed me as desirable, granted me absolution for all bestial impulses. A strange love: we each bask in the radiance of one another's magic. (p. 231)

Nietzsche too makes a discovery—that there can be therapeutic value in "applied philosophy."

We must look to *meaning*. The symptom is but a messenger carrying the news that *angst* is erupting from the innermost realm! Deep concerns about infinitude, the death of God, isolation, purpose, freedom . . . now break their bonds and bang at the doors and windows of the mind. (p. 232)

The novel reaches its climax when Breuer reveals (to Freud, not Nietzsche) his hedonistic fantasies, and Nietzsche, weeping, acknowledges a basic need for human contact. Patient and doctor embrace; Nietzsche returns to Switzerland to write his famous book about Zarathustra.

The author, Irvin Yalom, is a professor of psychiatry at Stanford University, an expert in group psychotherapy, and a persuasive writer. Using the format of a semihistorical novel allows him to express much wisdom and many doubts about the efficacy of psychotherapy and to explore sensitive issues regarding the doctor-patient relationship without having to worry about problems of confidentiality. But it exposes him to another risk—that of promoting historical inaccuracy. There undoubtedly will be readers of this book who believe it was Nietzsche and not Freud who catalyzed the discovery of psychoanalysis, just as there are those who believe Mozart was killed by Salieri after seeing Peter Shaffer's influential *Amadeus*. In a concluding "author's note," Yalom tries to sift fact from fancy by explaining who the characters in his novel actually were and that Breuer and Nietzsche never met. But in doing so he manages to perpetuate another myth: "In 1882, psychotherapy had not yet been born" (p. 305). In fact, not only has psychological healing been known for centuries, but there was widespread interest in moral treatment, persuasion, hypnosis, and other kinds of "talking cures" (2) before Breuer and Freud, especially in the nineteenth century.

Suttree (1979), by Cormac McCarthy. New York, Vintage Contemporaries, 1986, 471 pp., \$6.95 (paper).

Although classics in literature are often cited by psychiatrists for their penetrating insights into human activities and

emotions—Tolstoy, Dostoevsky, Sophocles, Shakespeare, Faulkner, and Joyce come to mind—we often fail to realize that contemporary works may attain such stature. Such books are at times hidden among the massive outpouring from the publishers, and do not become widely known. Cormac McCarthy's *Suttree* is such a novel, existing in some obscurity, but deserving of our closest attention and elevation into the canon of classics. It is a work I came to love years ago, and find myself returning to time and again.

Cormac McCarthy was born in 1933, served in the Air Force and attended the University of Tennessee. He has apparently lived most of his life in and around Knoxville and in west Texas. This is practically all the information that he allowed to become known about himself, before a *New York Times Magazine* interview (April 19, 1992). As psychiatric readers and reviewers, we cannot indulge in our sport of speculation about the writer's intrapsychic processes and their impact on his work. The novel must stand alone.

Suttree is the fourth of Mr. McCarthy's six published novels, and his masterpiece in terms of style and scope. His most recent work, *All the Pretty Horses* (1), has received excellent reviews and is accessible enough to win him the wide audience he deserves. If *Suttree* gains our attention through this process, we will all be enriched. McCarthy has been classified with the Southern Gothic writers, but he also has a place in the naturalistic tradition of the underclass with authors such as Jean Genet, Nelson Algren, Charles Bukowski, and William Kennedy.

Suttree is set in Knoxville, Tenn., and the surrounding country in the early 1950s. It covers an undetermined period in the life of (presumably) relatively young man, Cornelius Suttree, who has forsaken his genteel family to fish for a living and live among the homeless, alcoholic, and criminal elements of his community.

Although the content of *Suttree* can often be depressing, its language is rich and powerful. The novel is essentially a prose poem, humorous, colloquial, archaic, descriptive, and lyrical in turn. Echoes of Faulkner, Thomas Wolfe, and even Joyce can be heard, though McCarthy has his own voice. This superb writing is hard to convey in fragments; it is really necessary to read the entire book and experience its astonishing scope. However, the following passage from a brief idyll of Cornelius Suttree's can convey something of the book's delightful texture:

The willows at the far shore cut from the night a prospect of distant mountains dark against a paler sky. Halfmoon incandescent in her black galactic keyway, the heavens locked and wheeling. A sole star to the north pale and constant, the old wanderer's beacon burning like a molten spike that tethered fast the Small Bear to the turning firmament. He closed his eyes and opened them and looked again. He was struck by the fidelity of the earth he inhabited and he bore it sudden love.

As we follow the protagonist through his activities, almost every event reflects mortality and the weight of a reality unmoved by human desires or plans. We are often uncomfortable with this awareness. When Irvin Yalom wrote in *Existential Psychotherapy* (2) that "the clinician rarely encounters death anxiety in its stark form," he was speaking about many of our clinical experiences, but not about *Suttree*:

Recurrences of dreams he'd had in the mountains came and went and the second night he woke from un-

easy sleep and lay in the world alone. A dark hand had scooped the spirit from his breast and a cold wind circled in the hollow there. He sat up. Even the community of the dead had disbanded into ashes, those shapes wheeling in the earth's crust through a nameless ether no more men than were the ruins of any other thing once living. Suttree felt the terror coming through the walls. He was seized with a thing he'd never known, a sudden understanding of the mathematical certainty of death.

In this book, we are made to see what is often hidden from us in our life and work.

Cornelius Suttree appears to lead a life without the ordinary defensive processes people use to cope with the overwhelmingly difficult awareness of death. Before we are more than a few pages into *Suttree*, we see a suicide victim hauled from the river with a grappling hook, while Cornelius notices "with a feeling he could not name that the dead man's watch was still running." We soon learn that Suttree is an identical twin whose co-twin was stillborn, and that even as a child he "had already begun to sicken at the slow seeping of life." The intensity of his exposure to death rarely abates in 471 pages, although by the end he may have come to some kind of rapprochement. Suttree must attend his young son's funeral, is present at the violent death of several people close to him, and is near death himself on three occasions. After the last, a long, delirious bout with typhoid fever, he returns to his houseboat to encounter a corpse in his bed. So he lives, and while not triumphing over death, he may transcend it in a way, becoming less haunted and preoccupied. Such, at least, is the view of *Suttree*'s major literary critic, Vereen Bell (3). To the reader, the novel transcends through a paradox at its heart—even the most mortal scenes are written in language that is intensely alive. Sometimes the power of the world and all the life outside ourselves sickens us, but often in *Suttree* we are simply amazed at its vigor.

Suttree is certainly not a mere pathography—though alcoholism, anxiety, various personality disorders, dementia, delirium, and dysthymia are portrayed, and we may come to feel more empathy with the next unwashed, homeless patient we encounter in the emergency room. Diagnostic labels could be given to Suttree and, beyond them, we can see death anxiety as a major determinant of his behavior. Ultimately, however, explanatory systems fail and we encounter the mystery of another, separate person. While frustrating, this uncertainty can be a fruitful source of speculation, a creative force. A work of fiction that offers a nonclinical, nonexplanatory perspective on life reminds us not to settle for the easy answers in psychotherapy, pharmacotherapy, or research. *Suttree* does this, as well as taking up residence within the reader.

WILLIAM G. RYAN, M.D.
Birmingham, Ala.

Vox, by Nicholson Baker. New York, Random House, 1992, 156 pp., \$15.00.

In this age of 1-900 late-night promises, Nicholson Baker puts forth the real thing. His one-sitting novel, *Vox*, is a compelling exposure to sex and intimacy in a modern culture. Three thousand miles apart, a man and woman find the other's voice through a phone number in an adult newspaper advertisement. They talk for 4 hours about their experiences and methods of gratification, by no means all sexual. They are gentle with each other's fantasies, appreciative of creativity and humor. Their revelations clearly delight the teller as much as they do the recipient—he discloses, then she, then he, and so on; by the end, the giving and receiving are completely balanced.

Abby and Jim are the responsive, eloquent pair who place sensuousness on an even higher plane than they do sexuality. Indeed, it is difficult to imagine how they would make use of their keen perceptivity and playfulness if, after dialing 2-v-o-x at \$1.90 per minute, either was randomly connected to the type of person who seeks anonymous verbal sex. But, just who would that be anyway? The socially defective and frustrated or the erotically disposed, who craves immediate voice-to-ear closeness sealed in a fiber optic vacuum? Abby and Jim, as members of the latter group, certainly get their money's worth; they invite vulnerability by telling each other their most lovingly crafted fantasies and intensely personal experiences. Paradoxically, it may be the fleeting encounter with a stranger, rather than the sustained relationship with a partner, that is most hospitable to this type of exchange. With only a single sensory modality between them, trust develops quickly. The attunement is so perfect that, ultimately, they become afraid their connection will be destroyed if they talk again, let alone meet.

I suppose one could view all this as a commentary on the contemporary strategies of finding a mate. Or on the afflictions of the 1990s, such as AIDS. Or the hard-driving-profes-

sional's-stunted-capacity-for-intimacy. Or compulsive self-reliance in the midst of the disintegrating family. Are these at the core of the characters' dialogue, which emphasizes synchronous masturbation rather than intercourse? After all, one senses that they have left a trail of incomplete relationships behind them. Still, there is little desperation, little embarrassment. Any self-consciousness, of which personal advertisements typically reek, evaporates early in their conversation. If one feels a bit sorry for these two it is not because they are lonely people seeking salvation (they don't seem so) but, rather, because it is so rare that two people can understand the other's pleasure and language this deeply, and they may never meet or talk again.

Vox probably takes as long to read as the phone conversation lasts but is decidedly cheaper at 10 cents a page than the per-minute telephone rate. The book is ensconced in a stark black paper jacket that shows signs of violation within moments of purchasing. Is it a mere coincidence that the black paper picks up and subsequently announces every molecule of innocent moisture on one's hands? Is this some clever play on the concept of voyeurism?

Nicholson Baker has a stunning capacity to make the mundane vibrant. An earlier book, *The Mezzanine* (1), is also an exercise in compressed time; it has a single character whose one-way trip up an escalator serves as the stimulus for an exhilarating cascade of associations. In *Vox*, Baker transports his characters to eventual climax. For the reader who appreciates textured prose and creative verbal intercourse as well, gratification is imminent.

Letters to the Editor

Fluoxetine and Suicidal Preoccupation

SIR: Martin H. Teicher, M.D., and associates (1) reported the emergence of intense suicidal preoccupation during fluoxetine treatment, with an estimated incidence of 1.3%–7.5%. We reviewed all patients who received fluoxetine from the outpatient pharmacy at a Veterans Administration hospital during the period of April 1989 to April 1991. Policy dictated that patients must have failed more traditional pharmacotherapy or have another clear indication for use of fluoxetine. Fluoxetine was prescribed for 255 patients. Of these, six patients did not take the fluoxetine. Of the remaining 249, follow-up was obtained for 206, or 82%. One hundred thirty-six patients were studied retrospectively, and 71 patients were studied prospectively (beginning August 1990). Information was provided by the treating physician.

Physicians reported suicide history and any change in suicidal or homicidal ideation during treatment. In those few cases where an increase was reported, we spoke to the physician directly to obtain details. Patients included 183 men and 23 women, mean age=46 years (SD=1). Major depression was diagnosed in 159 patients (77%). Other diagnoses included 76 patients with substance abuse disorder (37%), eight with bipolar affective disorder, 25 with panic disorder (12%), 33 with dysthymic disorder (16%), eight with obsessive-compulsive disorder, 14 with borderline personality disorder, and 28 patients with other personality disorders (14%). In our patient population, 111 (54%) had a history of suicidal ideation and 45 (22%) had a history of suicide attempts.

Mean dose of fluoxetine was 30 mg/day (range=5–120 mg/day). Thirty percent of patients treated showed no real improvement taking fluoxetine. Two patients, one with schizophrenia complicated by depression and one with major depression, posttraumatic stress disorder (PTSD), borderline personality, and active alcohol abuse, became agitated and had a recurrence of suicidal ideation of the same quality as had occurred previously. One patient with borderline personality disorder had a similar recurrence of homicidal ideation. None of these patients had fluoxetine discontinued because of these thoughts, but none of them responded to fluoxetine, either. Of the remaining patients, 28% had a decrease in suicidal ideation, the others showed no change. However, not one of the patients showed the emergence of the intense, obsessive, violent suicidal preoccupation described by Dr. Teicher and associates (1).

Our patient population of more than 200 patients failed to demonstrate even a single case of intense suicidal preoccupation, despite the incidence of 1.3%–7.5% predicted by Dr. Teicher and associates. These results agree with those presented elsewhere (2). Fava et al. suggest that this phenomenon may be more rare than originally suggested or that it may be restricted to a subpopulation of those treated with fluoxetine. The patients in our study were a population with chronic psychiatric problems, treatment resistance, high comorbidity, and history of suicidal ideation and attempts. However, we had fewer women and fewer patients with borderline personality than most outpatient populations. Further studies of

large patient populations are necessary to confirm that de novo intense suicidal ideations are a side effect of fluoxetine.

Fluoxetine in Depersonalization Disorder

SIR: Symptoms of depersonalization may occur in a wide range of psychiatric disorders (1). Depersonalization disorder, however, with depersonalization symptoms in the absence of more common comorbid conditions, is an apparently rare syndrome (2). While depersonalization symptoms may respond to pharmacotherapies targeting various psychotic, affective, and anxiety disorders, little conclusive information exists regarding the psychopharmacologic treatment of depersonalization disorder (2, 3). Hollander et al. (3) reported on the successful use of serotonin reuptake blockers in six of eight cases of depersonalization. We report a case of depersonalization disorder that responded favorably to fluoxetine.

Mr. A, a 73-year-old man, complained that for many years he had experienced a "sense of unreality" and felt as though he were "in a fog." He reported feeling like a "disembodied intelligence" and described "seeing things as shapes and abstractions without emotional content." He described a sense of "dullness," with "colors not sharp" and reality seeming "less than full." He stated that "the world seems like a photographic negative." When he recalled events in his life, he felt as though he was "not in them." Eight years in psychodynamic psychotherapy had promoted useful insight but had not led to sustained symptomatic relief. Past history included probable panic attacks during adolescence without subsequent recurrence or persistent fear of having a panic attack. He admitted to mild, chronic anxiety, which he felt was related to his experience of reality as "dimmed." Mr. A denied depressed mood or anhedonia, and his symptoms fell short of *DSM-III-R* criteria for any specific anxiety or mood disorder, or other comorbid axis I diagnosis. For occasional insomnia he had taken flurazepam, 15 mg h.s., or trazodone, 25 mg h.s. His medical history included hypothyroidism and asthmatic bronchitis, for which he took levothyroxine, 0.25 mg/day, and intermittently theophylline, 200 mg b.i.d., respectively. The presenting psychiatric symptoms antedated these medi-

cal problems, and Mr. A experienced no exacerbation of the symptoms in relation to medication use.

Mr. A began treatment with buspirone, 5 mg/day, which increased to 5 mg b.i.d. after 1 week. After 2 weeks taking buspirone he discontinued it, believing it ineffective and becoming more anxious. Fluoxetine, 20 mg/day, was then prescribed. Four weeks later he described a clearing of the "fog," with reduction in associated anxiety. Three months later he reported feeling much better, and 8 months after initiation of treatment he continued to experience moderate improvement in depersonalization symptoms and marked reduction in associated anxiety. Asked to describe the improvement in his depersonalization symptoms, Mr. A replied that when he reflected on his life events, it seemed that he was "more in them."

This case lends support to the observation of Hollander et al. (3) that serotonin reuptake inhibitors may be effective for some patients with depersonalization disorder. Interestingly, although our patient experienced an overall reduction of his presenting symptoms following treatment with fluoxetine, he emphasized remission of anxiety to which he had admitted only secondarily on initial presentation. One might speculate that this patient's depersonalization disorder represented a subclinical anxiety disorder that was subjectively unmasked in the course of successful pharmacologic treatment. While this notion contrasts with the suggestion that panic is a lesser form of depersonalization (4), it is consistent with the concept of depersonalization as a dissociative disorder, in which dissociation serves a protective function to prevent the emergence of overwhelming anxiety.

Adverse Vascular Effects Associated With Fluoxetine

SIR: As briefly reviewed in the letter of J.A. Yaryura-Tobias, M.D., and associates (1) adverse vascular effects have previously been reported to be associated with the withdrawal of fluoxetine (Dista Products Company, *Fluoxetine Hydrochloride*, *Adverse Reactions*, 1989). These researchers subsequently reported eight cases of bleeding in patients diagnosed with obsessive-compulsive disorder and treated with fluoxetine. We would like to report symptoms in a single patient possibly associated with fluoxetine. The symptoms were recurrent over two trials of medication. No such symptoms were ever noted prior to fluoxetine treatment.

Mr. A, a 38-year-old man, was involved in psychotherapy with a diagnosis of both dysthymia and associated char-

acterologic dysfunction, including symptoms consistent with the diagnosis of obsessive-compulsive disorder. Fluoxetine treatment was initiated at a dose of 20 mg/day and increased during the second month to 40 mg/day. The patient developed inflammation and apparent bruising of the great and neighboring two toes of both feet. At the same time, the patient developed sporadic spontaneous epistaxis at a frequency of approximately two times per week, which resolved with the application of external pressure.

Because of an absence of therapeutic response and reticence on the part of the patient to increase dosage, fluoxetine treatment was discontinued after 3 months. Psychotherapy continued without additional biological treatment. The physical symptoms remitted concomitantly. During this first fluoxetine trial, no association between these symptoms and fluoxetine was hypothesized.

Fluoxetine treatment was reinitiated after approximately 8 months at a dose of 20 mg/day, increasing to 40 mg/day and then 60 mg/day over a 2-month period. Spontaneous epistaxis and inflammation and bruising of the patient's toes with infection of the toes reappeared. On this occasion, a dermatologic consultation was sought and clavulanic acid, 250 mg t.i.d., was prescribed. The infection resolved over 7 days. However, inflammation and bruising consistent with vascular spasm phenomena (acrocyanosis) remained. The epistaxis, at a frequency of approximately two times per week, again was controlled with externally applied pressure.

Further medical evaluation, including hematologic and thyroid studies, indicated no abnormalities. Laboratory tests revealed a platelet count of 195,000/mm³, a WBC count of 3600/mm³, and a hemoglobin level of 14.1 g/dl. Fluoxetine dosage was increased to 80 mg/day. With no therapeutic effect noted after 30 days, the fluoxetine was tapered over a 4-week period. Epistaxis as well as aforementioned bruising and inflammation diminished with reduction in dosage and disappeared when fluoxetine was reduced to 20 mg/day.

We believe that this case report supports the concerns of other authors (2-4) regarding potentially significant bleeding problems associated with fluoxetine treatment.

Phenelzine Treatment of Depression in Parkinson's Disease

SIR: We present the case of a patient treated with the monoamine oxidase inhibitor (MAOI) phenelzine and L-dopa-carbidopa combination who showed marked improvement in both the Parkinson's disease and depression.

Mr. A, a 72-year-old man, was admitted to a psychiatric unit. He had a 30-year history of progressive Parkinson's disease and a 2-year history of treatment-resistant agitated depression. He had been unresponsive to antidepressants (amitriptyline, nortriptyline, protriptyline, desipramine, fluoxetine, tranylcypromine, and trazodone) and anti-anxiety agents (alprazolam, lorazepam, and clonazepam). Neurological examination revealed resting tremors of all extremities, shuffling, unsteady gait, and stooped posture. Primitive reflexes were also present. Neuropsychological testing revealed moderate to severe deficits in orientation, memory, attention, and abstract thinking. Magnetic resonance imaging (MRI) revealed mild atrophy and increased signal in the periventricular white matter. The diagnosis of Parkinson's disease with dementia was made. Mental status examination was conducted. His mood was depressed and extremely anxious, but he denied suicidal plans. He was not hallucinating or delusional. He was uncooperative and required a great deal of nursing staff assistance.

Initially Mr. A was treated with L-dopa-carbidopa combination, 25/100 mg t.i.d., for depression and metoclopramide, 10 mg t.i.d., for hiatal hernia. Over the next 5 weeks, his medications were adjusted to a final regimen of phenelzine, 15 mg h.s., L-dopa-carbidopa combination, 25/100 mg b.i.d., and sucralfate (phenelzine was associated with gastrointestinal upset). By the seventh week he was no longer depressed and was able to attend independently to himself. He improved enough to ambulate around the hospital grounds without assistance. Because of family problems, Mr. A was discharged to a nursing home.

There has been a recent significant trend in the treatment of Parkinson's disease to use the selective MAO-B inhibitor selegiline to slow the progression of the disease and enhance the efficacy of L-dopa (1). The combination of nonspecific MAOIs and L-dopa has been avoided due to the reported risk of serious side effects, specifically hypertensive crisis. However, the L-dopa-carbidopa combination, containing a peripheral dopa decarboxylase inhibitor, may allow safer use of MAOIs. Therefore, use of a nonspecific MAOI may be a fortuitous agent to treat both Parkinson's disease and depression. The patient described here had longstanding Parkinson's disease and a history of tricyclic-resistant depression. This patient's mood disorder was consistent with atypical depression (2), a form of depression common among patients with Parkinson's disease. MAOIs are useful in treating tricyclic-resistant depression (3), atypical depression (4), and depression associated with dementia (3). Treatment with phenelzine and L-dopa-carbidopa combination resulted in substantial reduction of our patient's depression and movement disorder. Mr. A's clinical improvement may be related to the mechanism of action of phenelzine. Acting as both an MAO-A and an MAO-B inhibitor, phenelzine may have beneficial effects on both depression and movement disorders related to insufficient norepinephrine, serotonin, and dopamine. This case suggests that the combination of low-dose phenelzine and L-dopa-carbidopa combination can be a safe alternative drug regimen for the pharmacological treatment of depression in patients with Parkinson's disease.

Antidepressants, Panic Disorder, and PTSD

SIR: The phenomenology of posttraumatic stress disorder (PTSD) flashbacks and panic attacks is similar (1), and flashbacks and panic attacks often coexist (2, 3). However, antidepressants are effective for the treatment of panic disorder (4) and relatively ineffective for PTSD. While both imipramine and phenelzine significantly improved PTSD symptoms in a study by Frank et al. (5), in other controlled studies amitriptyline showed only modest results with respect to PTSD symptoms (3), and desipramine did not improve anxiety or other PTSD symptoms (6). We report a case in which desipramine blocked recurrent panic attacks but did not prevent the development of PTSD.

Ms. A, 21 years old, had a 2-year history of panic disorder. Four of her five siblings also had panic attacks. Her unprovoked panic attacks were marked by anxiety, shortness of breath, palpitations, chest discomfort, dizziness, trembling, and fears of dying, losing control, and going crazy. Her attacks occurred daily. She became panic free when treated with imipramine and later with desipramine, after imipramine was discontinued due to side effects. After 1 year of desipramine treatment with doses between 200 and 250 mg/day, she became pregnant and discontinued medication. She then became severely symptomatic. Ms. A was restarted on desipramine and again became symptom free. After another year of treatment, she was abducted and raped. While still panic free she developed PTSD, with typical symptoms that included psychic numbing, nightmares, startle response, hypervigilance, avoidance of situations that reminded her of the abduction, and intrusive thoughts of the rape. She received counseling for PTSD and continued desipramine treatment, still panic free. Her PTSD symptoms gradually subsided over 2 years; however, her panic attacks recurred 3 years after the trauma when tricyclic antidepressants were discontinued. She responded to treatment with fluoxetine.

Desipramine successfully blocked panic attacks in our patient before, during, and after a traumatic event but did not prevent the development of PTSD. While only a single case, this unusual set of circumstances suggests that panic attacks and PTSD do not share a common diathesis.

Taking Chronic Fatigue Syndrome Seriously

SIR: The recent article by Susan E. Abbey, M.D., and Paul E. Garfinkel, M.D. (1), on neurasthenia and chronic fatigue syndrome contains many statements suggesting that chronic fatigue syndrome is a trivial illness and not worthy of serious medical or psychiatric consideration. Stating that chronic fatigue syndrome is an "illness behavior" molded by social pressures does a great disservice by dismissing the suffering of patients with this illness because of a lack of understanding of its etiology. The role of the physician should be to attempt to alleviate pain and suffering rather than to belittle it.

I feel that the article is unfair and selective in its treatment of the topic by reworking today's knowledge of chronic fatigue syndrome with an outdated metaphor. While it may be that the illness is not new, correlations with earlier clinical descriptions should not be made merely to reassign a pejorative stigma. This paper continues a tradition of ridiculing chronic fatigue syndrome (2). Considerable progress has been made in understanding many medical conditions previously felt to be of psychosomatic origin. While the etiology of chronic fatigue syndrome may be elusive, it is a syndrome worthy of our research efforts exactly because of its complex nature.

The argument for a medical etiology for chronic fatigue syndrome has been trivialized. No comment is made of the abnormal natural killer cell cytotoxicity (3), immune activation markers (4), and the presence of interferon in CSF (5). An attempt has been made to reduce modern immunologic advances to having "captivated the imagination of both the public and medical professionals." That we do not have full understanding of the role immunology plays in chronic fatigue syndrome should not dismiss its importance. It is not far-fetched to imagine that we are advancing into an era of medical science where symptoms are seen to result from immune system (cytokine) activation rather than the tissue destruction traditionally sought by the pathologist.

It is not the fault of the patient that chronic fatigue syndrome does not fit any conventional disease model. It cannot be seen as an ordinary infectious disease or life-threatening immunodeficiency. But it also cannot be seen as simple depression or a culturally determined illness behavior. The brain is tremendously complex, and modern medicine as a discipline should move beyond the antique dualistic model of "organic" versus "psychologic." The exciting element of science is the possibility to study that which is unknown. The beauty of medicine is to offer compassion without trivializing human suffering with outmoded psychologic constructs. Chronic fatigue syndrome offers us the opportunity to do both.

DAVID S. BELL, M.D.
Rockville, Md.

SIR: The recent article on neurasthenia and chronic fatigue syndrome by Drs. Abbey and Garfinkel contains a glaring distortion of the facts. The source of the error is clear from the authors' description of patients with chronic fatigue syndrome as those who are unable to continue full-time work and those who suffer from fatigue, fever, sore throat, muscle aches, headaches, arthralgias without redness or swelling, neuropsychological complaints, and sleep disturbance. In fact, at least 20%-25% of patients with chronic fatigue syndrome are unable to work at all for many years, suffer seizures, and cannot walk normally. In some of these patients the peripheral neuritic pain and myalgia are so severe that suicide may be resorted to. Joint redness and swelling does occur, and patients may become totally economically dependent on their families.

Furthermore, like AIDS, the disease leads to secondary disorders caused by the immune deficiency aspect of the disorder, i.e., thyroiditis, irritable bowel, adrenal deficiency, and, in a number of cases, measurable and observable changes in brain function determined by MRI and PET scan studies of blood flow to the brain (1). Komaroff (2) has studied 350 patients and evaluated 30 epidemic outbreaks. He concluded that the disorder, which may be precipitated by stress or infection, is organic. He discovered that 80% of patients with chronic fatigue syndrome are infected with human herpesvirus type 6 (HHV-6). Hyde (3) has written a scholarly article comparing historically the present epidemic, which the British and Canadians more appropriately label "myalgic myeloencephalitis," to epidemics of poliomyelitis.

From personal observation of 50 cases, it is clear that the discussion by Dr. Abbey and Dr. Garfinkel of chronic fatigue syndrome as a "cultural phenomenon" only addresses the mild form of the disease. In summary, the article is reminiscent of early articles on multiple sclerosis, before it was understood, when it was discussed as an expression of hysteria because it evidenced affective lability and occurred frequently in females.

WELLS GOODRICH, M.D.
Rockville, Md.

SIR: Dr. Abbey and Dr. Garfinkel proposed that chronic fatigue syndrome represents a medical fad and that, like neurasthenia in earlier times, it is the product of an unwitting collusion between physicians and patients.

In contrast to the widespread acceptance the diagnosis of neurasthenia enjoyed, chronic fatigue syndrome has not been a welcome pigeonhole for ambiguous conditions. Derided as the Yuppie flu, it has met with resistance by nonpsychiatric clinicians who tend to invoke psychiatric causes when faced with diagnostic and treatment failures.

There is an urgent issue here that offers a new task for the bioethicist. The assertions of Drs. Abbey and Garfinkel, that "the diagnosis of chronic fatigue syndrome, because of its implied 'organicity,' is attractive to patients and is tenaciously upheld" and, like the neurasthenia it resembles, offers "the only socially legitimate excuse for abandoning the workplace and the pursuit of achievement," risks reinforcing the suspicion of malingering that hangs over chronic fatigue syndrome. Should not Dr. Abbey and Dr. Garfinkel be obliged to comment on their possible reinforcement of this suspicion?

Drs. Abbey and Garfinkel stated, on the basis of data by Kleinman, that "despite pharmacological treatment of the associated psychiatric disorder, neurasthenic symptoms [which they equated with chronic fatigue syndrome] persist." Although this appears strikingly to confirm organicity, the authors concluded that chronic fatigue syndrome is simply "illness behavior" on the ground that, as Kleinman also reported, "only those patients improved who resolved a major family or work problem." (No reason is given not to assume the reverse, that the patient in remission is more capable of resolving family or work problems.)

The finding of Gold et al. (1), cited by Dr. Abbey and Dr. Garfinkel, that there is no difference in HHV-6 antibody titers between chronic fatigue syndrome patients and control subjects, must be compared with the highly significant difference more recently found by Landay et al. (2). Still more recently, Buchwald et al. (3), on the basis of a study of 229 patients, concluded that "the several objective neurologic, immunologic, and virologic findings make a diagnosis of purely psychological illness unlikely," stating further that chronic fatigue syndrome "probably is a heterogeneous illness that can be triggered by multiple different genetic and environmental factors (including stress, toxins, and exogenous infectious agents), all of which can lead to immune dysfunction and the consequent reactivation of latent viruses."

BERNARD APFELBAUM, PH.D.
Berkeley, Calif.

SIR: In their article on chronic fatigue syndrome Drs. Abbey and Garfinkel argue that the syndromes of neurasthenia and

chronic fatigue share many similarities. They argue critically that both diagnoses reflect the dominant scientific models of the day. Then, using a dominant cultural model—gender—the authors argue that the expanding role of women and conflicts between women's ambition and social possibilities contribute to this diagnosis. They conclude that chronic fatigue syndrome is a culturally sanctioned form of illness behavior and that the majority of these patients suffer from a primary psychiatric disorder.

There are several concerns we have with this article. The authors' conclusions, although reasonable, do not follow from their argument. Although there are similarities between neurasthenia and chronic fatigue syndrome, it does not follow that the two conditions or their fate are the same. Likewise, dominant models, whether they be scientific or cultural, should not be accepted or rejected outright but, rather, need to be carefully evaluated on the basis of available data.

The data that were presented are not convincing. The conclusion that the majority of these patients suffer from a primary psychiatric disorder or depression is controversial. Although Drs. Abbey and Garfinkel cited studies that indicate a high prevalence of psychiatric disorder, especially depression, these studies used instruments—the National Institute of Mental Health Diagnostic Interview Schedule (DIS) and the Structured Clinical Interview for DSM-III-R (SCID)—that were never designed to diagnose psychiatric illness in medically ill patients (1, 2). It remains unresolved whether the so-called vegetative symptoms in these conditions are part of a psychiatric or medical disorder. Likewise, the Hickie study showed that a minority of the patients (45%) had a coexisting major depression and even then it raises the question as to whether this is part of a biological disorder. The role of depression or psychiatric illness is far from clear in these disorders.

The authors too quickly dismiss the biological significance of this syndrome. Many studies report immunological abnormalities in both the humoral and cellular response in chronic fatigue syndrome. The pathophysiology of this syndrome remains unclear. For centuries syphilis was thought to be a psychiatric disorder until *Treponema pallidum* was discovered. Unsuccessful attempts to identify the pathophysiology of an illness does not mean that it is a psychiatric condition, nor can one assume that future research will be unsuccessful.

Our main concern about the article is that the authors appear to eliminate prematurely the biological significance of the syndrome and simultaneously endorse a social and psychological explanation. Our main point is the need for a biopsychosocial approach. This is especially true of chronic fatigue syndrome, which probably consists of a heterogeneous group of illnesses. Progress will be made on the basis of well-designed studies that set out, from an unbiased position, to further clarify and understand the biological, psychological, and social interactions of this complex syndrome.

DON L. GOLDENBERG, M.D.
MAUREEN GALVIN-NADEAU, R.N., M.S., C.S.
Wellesley, Mass.

SIR: Drs. Abbey and Garfinkel provide an interesting historical review of neurasthenia, but their conclusions about chronic fatigue syndrome seem speculative, demeaning, and inaccurate in the following ways:

1. The authors omitted recent medical research into the etiology of chronic fatigue syndrome. This includes polymer chain reaction techniques that show a possible association between chronic fatigue syndrome and a retrovirus (1) and immune system abnormalities and activation markers (2).

2. The authors failed to examine the research on neuropsychological abnormalities. MRI scans have revealed abnormalities (3), as have single photon emission computed tomography (SPECT) and brain electrical activity mapping scans (4). Reduced ability to acquire new information, as well as drop in IQ, have been seen (unpublished 1989 paper by S. Bastien).

3. The authors concluded that a majority of chronic fatigue syndrome patients will have an identifiable psychiatric disorder. Patients may develop psychiatric difficulties once they acquire chronic fatigue syndrome, but a recent study has shown that the incidence of pre-illness affective or other psychiatric disorders is no greater than in the general population (5).

Our clinical experience suggests that there are substantial differences between chronic fatigue syndrome-related depression and primary major depression. For example, in the former, sleep disorders may involve non-REM sleep rather than the REM disturbance found in major depression (6). The fatigue in chronic fatigue syndrome is accompanied by intense frustration at not functioning well, rather than the apathy and anhedonia experienced by patients with major depressive disorder.

4. The authors imply that chronic fatigue syndrome is both attractive to and has social value for chronic fatigue syndrome patients. This is simply absurd. We have rarely seen secondary gain or social value associated with chronic fatigue syndrome. The price of chronic fatigue syndrome, as with other chronic illnesses, is loss and estrangement from "normal" life. Chronic fatigue syndrome engenders shame, frustration, and stress over not functioning at pre-illness levels.

5. Particularly offensive is the authors' attitude toward women with chronic fatigue syndrome and their conclusion, which is purely speculative and not labeled as such, that chronic fatigue syndrome represents an escape from the stress of balancing work and family obligations. This notion is Victorian. The authors fail to apprise us of how and where they obtained their data on chronic fatigue syndrome, the nature of their study sample, and how they gained their clinical expertise in chronic fatigue syndrome. Finally, how did they conclude that neurasthenia was psychosomatic?

We hope that the authors, in pursuit of their metaphors, will recall Koranyi, who surveyed 4,000 psychiatric patients and found that half had major medical illnesses. One-third of primary care physicians and half of the psychiatrists missed the physical diagnoses.

SIR: Plaintiffs' attorneys seasoned by clients claiming monies for alleged industrial and similar injuries will spot familiar scenarios among the neurasthenics portrayed by Drs. Abbey and Garfinkel.

WILLIAM F. SHEELEY, M.D.
Phoenix, Ariz.

SIR: Drs. Abbey and Garfinkel produced another review linking chronic fatigue syndrome to neurasthenia and proposed that rapid changes in female roles may explain such syndromes. We have demonstrated, however, that any excessive female:male sex ratio is largely an artifact of tertiary referral practice, as the sex ratio in primary care is only 1.3:1 (1). They were dismissive of evidence of immunological dysfunction (2, 3), suggesting that these data simply represent medical fashion. We have demonstrated immunological abnormalities in patients with chronic fatigue syndrome as compared with both normal controls and patients with major depression (2, 4). Further, the demonstration of abnormal cytokine production in patients with chronic fatigue syndrome (5) suggests that an intriguing pathogenesis may underpin "acquired neurasthenia." While no conclusive studies exist, psychiatrists should be more cautious before dismissing such data.

With regard to natural history and treatment outcome, Dr. Abbey and Dr. Garfinkel ignored available studies (1, 6) and relied solely on "clinical experience." Interpretative hypotheses were proposed, despite others' reservations that treatments based on such hypotheses are largely unsubstantiated (7). Pronouncements that improvement depends on resolution of "a major family or work problem" are not consistent with the response of some patients to intravenous immunoglobulin (6).

Although the debate concerning chronic fatigue is one to which psychiatrists should contribute, psychological hypotheses that arbitrarily ignore or discount other models should be avoided. We (8), like others (9), have emphasized the need for collaborative efforts in which immunological, virological, neurohormonal, and psychological hypotheses are evaluated concurrently.

IAN HICKIE
ANDREW LLOYD
ANDREW WILSON
DENIS WAKEFIELD
Little Bay, New South Wales, Australia

SIR: Dr. Abbey and Dr. Garfinkel reviewed the similarities between chronic fatigue syndrome and neurasthenia and concluded that, in many cases, chronic fatigue syndrome represents a culturally sanctioned form of illness behavior. Although they acknowledged that a medical basis for chronic fatigue syndrome may be identified in some patients, they argued that the majority of patients suffer from a primary psychiatric disorder, a stress reaction, or a form of illness behavior. They then suggested that this may be due to changes in the role of women and the impact of a materialistic culture.

Although we agree that psychiatrists need to be aware of the possible psychosocial etiology of chronic fatigue, we also feel that it behooves us to be very careful before concluding that a patient's symptoms are largely psychogenic. The psychiatrist must also carefully consider whether the fatigue may be a symptom of an underlying undiagnosed medical illness, such as endocrine disease, HIV infection, Lyme borreliosis, malignancy, mononucleosis, collagen vascular disease, or some other as yet unidentified postinfectious syndrome. Because much in medicine is still unknown, psychiatrists need to maintain an open mind to the multiple determinants of unexplained physical symptoms.

MICHAEL R. LIEBOWITZ, M.D.
DONALD F. KLEIN, M.D.
New York, N.Y.

Dr. Abbey and Dr. Garfinkel Reply

SIR: It is important to address the view that we are "trivializing" or "demeaning" chronic fatigue syndrome by examining the role of culture in the development and popularization of this diagnosis and by comparing it with neurasthenia. In previous work (1) we proposed that chronic fatigue syndrome is a heterogeneous disorder, and we encouraged its study from a variety of perspectives. We advocated the study of both those patients with a primary post-viral syndrome and, what we believe is the larger group, those patients with primary psychopathology or psychophysiological reactions account-

ing for their symptoms. The recognition that many of the patients currently carrying self- or physician diagnoses of chronic fatigue syndrome have underlying psychopathologies is not an invalidation of the existence of the diagnosis in some patients nor is it a trivialization. Rather, it offers the potential of advancing research into the array of disorders that currently fall within the chronic fatigue syndrome rubric. Closer attention to psychiatric and psychosocial factors will allow the detailed study of a more homogenous group of chronic fatigue syndrome patients and is likely to maximize the chance of identifying a pathogenic agent or consistent abnormalities of immune functioning, should they exist, and of correlating these abnormalities with clinically significant variables. The study of those individuals with primary psychopathology will deepen our understanding of the processes of somatization, illness behavior, hypochondriasis, and somatic presentations of the major mental illnesses, all important areas which are costly to society in significant individual and family suffering and use of health care resources.

Dr. Bell's explicit contention and the implicit contentions of Drs. Goodrich and Apfelbaum that conceptualizing chronic fatigue syndrome in some patients as a form of culturally sanctioned illness behavior is consistent with dismissing their suffering reflects a profound lack of understanding of the distress, functional disability, and suffering that are well-documented to be associated with illness behavior (2). Dr. Apfelbaum raises ethical concerns about "the suspicion of malingering which hangs over chronic fatigue syndrome" and asserts that we are encouraging this. While the consideration of malingering or factitious symptom production or reporting may be part of the differential diagnosis for almost any medical condition, we do not believe that a discussion of illness behavior is equivalent to an assertion that patients are malingering. We reject Dr. Bell's assertion that we are "belittling" or "blaming" patients and continuing a "tradition of ridiculing" chronic fatigue syndrome by exploring these themes. His perspective is representative of the larger process of politicization of the diagnosis which only supports research emphasizing the organic aspects of the syndrome (1) and dismisses the important role of psychological factors which are clearly relevant in all medical diseases.

We agree with Dr. Kaplan and colleagues that the role of depression or psychiatric illness is far from well defined, and we have discussed the complex relationship between depression and chronic fatigue syndrome elsewhere (3). This is a subject which is benefiting from improved research methodology, including the use of case definition criteria for chronic fatigue syndrome and an improved understanding of the role of instruments such as the DIS and SCID in the psychiatric assessment of medically ill patients.

We reject Dr. Goodrich's assertion of a "glaring distortion of the facts" and his personal belief in a more severe form of the illness accompanied by seizures and joint redness and swelling, for which there is no scientific support in peer-reviewed publications.

Finally, it has been asserted that we have too quickly dismissed the biological significance of the syndrome. We must emphasize that it was *not* the purpose of the article to critically review the biological research literature. The biology of chronic fatigue syndrome is a complex and problematic area characterized by significant difficulties in research design and methodology which has, to date, produced few studies with solid, replicable findings or findings that correlate with clinical status. The references cited by the correspondents demonstrate many of the problems of research in this area. Due to the limitations of space, we cannot fully critique all of the studies here but will cite a few examples. The finding of Lloyd et al. (Dr. Bell's reference 5) of

elevated interferon-alpha in chronic fatigue syndrome patients is no longer statistically significant when an appropriate Bonferroni correction is made for the multiple comparisons undertaken. The finding did not correlate with duration of symptoms or severity of disability, and in their discussion Lloyd et al. noted that other investigators had either not found this abnormality or demonstrated it in only a small subgroup of chronic fatigue syndrome patients. Klimas et al. (Dr. Bell's reference 3) also noted the variability in findings between investigators. Goldstein's report (Dr. Goodrich's reference 1) and Bastien's report (cited by Ms. Saltzstein and associates) have yet to be described in a peer-reviewed forum. Hyde's study (Dr. Goodrich's reference 3) involved a nonblind assessment of patients, emphasized subtle neurological abnormalities although the patients were not examined by a consultant neurologist, and focused on an epidemic which has unclear relevance for the current sporadic form of the illness. There are no replicated studies that have convincingly demonstrated a viral etiology for the disorder. As with Epstein-Barr virus, it now appears that the primary infection with HHV-6 occurs in most individuals in early life, and the meaning of HHV-6 reactivation in approximately 70% of the subjects of Buchwald et al. (Dr. Apfelbaum's reference 3) is unclear. As they note, it may be an epiphenomenon, secondary to immune dysfunction or have no relation at all to a patient's symptoms. To date, there has been a failure to replicate the retroviral findings. Significant abnormalities of neuropsychological functioning have not been reported in peer-reviewed publications (4). Our own work has documented abnormalities on SPECT scanning in a subgroup of patients with chronic fatigue syndrome but the significance of this finding is unclear (5). Moldovsky's report (Ms. Saltzstein and associates' reference 6) focused on a small number of patients, and studies are currently underway in a number of centers that document a wide range of abnormal sleep findings. No studies in the literature have used adequate psychiatric control groups, which would be an important consideration given the documented abnormalities in immunology, neuroimaging, and neuropsychology that have been found in major depression (3). We are currently pursuing investigations of patients with chronic fatigue syndrome and those with major depression on a variety of immunologic measures in order to help clarify this issue.

Clearly, it is important to study this syndrome further from an integrative biopsychosocial approach using well-designed studies. In this paper, we sought to emphasize the importance of studying social factors in the genesis and shaping of chronic fatigue syndrome.

Pharmacotherapy of Agitation in Dementia

SIR: We appreciate the carefully designed study by Emil F. Coccaro, M.D., and associates (1) that reported the relative efficacy and side effects of three pharmacotherapies of agitation in dementia. The authors mustered a large sample of well-assessed patients with severe dementia, screened them meaningfully for the independent variable, allowed for dosage adjustment, maintained double-blind conditions, and attended to the validity of the rating process. Their discussion of the background and results anticipated the publication of a scholarly review (2) that provides useful context for such discussion.

Despite the strengths of parallel-group studies in this area, they have major drawbacks in application to individual patients. A physician eager to use these results for a difficult patient would need to know whether his patient belonged to the universe of patients screened and included in this study. If his patient had one of the less common forms of dementia included (for instance, Korsakoff's), he would not know whether the mean outcome data of the whole group had predictive value in his situation. He also would not know from a parallel-group study (as these authors pointed out) whether their finding of "no difference between medications" applied to any individual case.

We recently completed a series of intensive (N-of-1) studies (3) designed to avoid the problems of using extensive study results (paper in preparation). Like Dr. Coccaro and associates, we treated dementia patients with oxazepam and diphenhydramine and used thiothixene instead of haloperidol. We also maintained double-blind conditions and used frequent ratings (shift-by-shift ratings of resistiveness). We crossed over between optimal dosages of each medication often enough to provide several presentations of the most effective.

We found that this strategy was practicable and well accepted in our setting. Of 10 patients admitted, seven remained free of serious medical illness long enough to analyze. One patient was dropped due to improvement during placebo administration. Another did not respond to thiothixene, oxazepam, or diphenhydramine. Of the remaining five, four responded best to thiothixene, 2-4 mg/day, and one responded equally to diphenhydramine, 150 mg/day and thiothixene. None were improved on treatment with oxazepam. Global ratings before and after these trials confirmed that improvement was not achieved by sedation. These findings were transmitted to the clinical team as medication recommendations. Born of long and methodological observation, they survived the inevitable next episodes of resistiveness. In 1- to 2-year follow-up, these medication assignments have, in general, been followed.

Our aggregate results closely mirror those of two reviews of medication trials for agitation in demented patients (4, 5). Antipsychotics have the best, but modest, efficacy, whereas benzodiazepine sedatives have little to offer.

We believe clinical decisions should be guided by the widest experience with similar patients, but behavior disorders in dementia often pose challenges that defeat this guidance. Under such circumstances, an N-of-1 trial may be a reasonable approach. For research use, it may provide (as in this case) treatment evaluation that is economical; for clinical purposes, it may instill confidence that the final treatment is indeed optimal in the long run.

Dr. Coccaro and Dr. Mohs Reply

SIR: We agree with Dr. Herz and associates that the response of demented patients to various pharmacotherapies for agitation may be highly individual. Given our current state of knowledge, the N-of-1 crossover treatment studies they propose may be the most practical way to identify the best treatment for a single patient. The need for such an approach, however, is a reflection of our poor understanding of "agitated" behavior both biologically and behaviorally. The patients included in our study and in others undoubtedly had a variety of neuropathologic and neurochemical abnormalities. The associated behavioral problems included verbal and physical aggressiveness, pacing, wandering, and anxious and other behaviors. Whether biologic, behavioral, or clinical diagnostic variables could be used to select the most effective agent for a given patient or subgroups of patients remains to be determined. At present we know of no studies demonstrating such treatment specificity. We would like to add that our own study indicates that oxazepam and diphenhydramine are of use for at least some patients.

ECT and Delirium in Parkinson's Disease

SIR: Jaehoon J. Oh, M.D., and associates (1) described the development of a reversible delirium in seven of 11 patients with Parkinson's disease treated with ECT for "psychiatric illness." In six patients, delirium was so severe that ECT had to be discontinued. They considered the possibility of "a particular vulnerability to the cognitive side effects of ECT" in this patient population. They, however, did not report the medication status of their patients, which may be a factor in their observations.

The response of Parkinson's disease to ECT is reported to be related to an increase in dopamine levels or enhanced dopamine receptor sensitivity (2). Evidence from the animal literature supports this hypothesis (3). Should dopamine transmission, or brain levels of dopamine, become excessive, a delirium or toxic psychosis, such as the one observed with excessive dosages of dopamine agonists, may be precipitated (4). Our preliminary results indicate that coadministration of ECT and antiparkinson agents increases the likelihood of de-

lirium (5). Reducing these agents to one-half their dosage prior to initiating ECT prevented the occurrence of such toxicity without compromising the motoric improvement of Parkinson's disease.

We suggest that standing dosages of dopamine agonists be reduced prior to initiating ECT in order to decrease the incidence of delirium described by Dr. Oh and associates.

IANNIS M. ZERVAS, M.D.
MAX FINK, M.D.
Stony Brook, N.Y.

SIR: In a recent communication to the *Journal* (1), we reviewed the evidence for enhanced dopaminergic neurotransmission following a course of ECT (2, and unpublished work of Rudorfer et al.) and wondered whether this could explain the delirium seen in a patient taking dopaminergic medications following completion of ECT. Illustrating our point is the patient series reported recently by Dr. Oh and associates. They described a retrospective analysis of 11 patients with Parkinson's disease who underwent ECT for associated mood disorders. Although most patients benefited from the treatment, they demonstrated an unexpectedly high (64%) incidence of post-ECT delirium, requiring the discontinuation of ECT in six patients.

One explanation for this untoward reaction to convulsive therapy could lie in the concurrent L-dopa-carbidopa combination taken by most of the patients. Enhanced responsivity of dopamine receptors, which has been demonstrated following ECT in parkinsonian as well as depressed patients (2), could excessively potentiate the effects of the dopamine precursor, L-dopa. Moreover, the patients with organic hallucinosis and mania may have had excessive dopaminergic transmission at baseline. While ECT typically exerts an antipsychotic clinical effect, presumably through direct or indirect inhibitory actions on mesolimbic dopamine pathways (our unpublished work), the impact of simultaneous dopaminergic medications is unknown. Also at issue is the question of whether ECT-associated increased permeability of the blood-brain barrier could influence the rate or extent of entry of concurrent medications into the central nervous system.

While Dr. Oh and associates limited their references of ECT use in Parkinson's disease to case reports from the 1970s, the more recent literature includes two highly successful trials of ECT in depressed patients with Parkinson's disease (one reported in the *Journal* [3]), including the only sham-ECT controlled trial (4). While the primary clinical intent was treatment of the mood disturbance, significant concomitant

improvement in the motor signs of Parkinson's disease was also observed (3, 4). Further trials are indicated to define the role of ECT in the treatment of Parkinson's disease (5) with or without associated mental disorders, including the potentially therapeutic or toxic contribution of concurrent medications.

MATTHEW V. RUDORFER, M.D.
HUSSEINI K. MANJI, M.D.
WILLIAM Z. POTTER, M.D., PH.D.
Bethesda, Md.

SIR: We read with great interest the recent report by Dr. Oh and associates. The authors observed a high incidence of ECT-induced delirium in patients with Parkinson's disease. Consistent with their observations, we recently described the development of an interictal ECT-induced delirium in seven consecutive depressed patients with Parkinson's diseases who received ECT (1). The deliriums were clinically significant, lasting between 7 and 21 days after the ECT was stopped, and were characterized by a substantial lowering of Mini-Mental State Examination scores (mean=11, range=10-23). For the entire group, the number of ECT treatments administered after the onset of the deliriums correlated with the durations of the deliriums ($p=0.03$). There did not appear to be an association between the onset or duration of the delirium and the patient's age, duration of Parkinson's disease, or the daily dosage of L-dopa.

To further examine the incidence of ECT-induced interictal delirium in patients with Parkinson's disease, we recently completed a prospective study that compared the incidence of delirium in 20 depressed patients with a history of a cerebrovascular accident with 20 age-matched depressed Parkinson's patients. The ECT technique has been previously described (1) and was identical for both groups of patients. The diagnosis of ECT-induced delirium was made by a physician on the ECT service on the basis of information obtained from the clinical treatment team and from the serial mental status examinations. The pre-ECT Mini-Mental State scores were similar for both groups (mean=27.2 for patients with cerebrovascular accident versus mean=27.6 for patients with Parkinson's disease).

An interictal ECT-induced delirium occurred in five (25%) of 20 patients with cerebrovascular accident compared with 17 of 20 (85%) patients with Parkinson's disease. A preliminary analysis of the data did not reveal a significant correlation between the time of onset or duration of the deliriums and the patients' sex, daily dosage of L-dopa, or duration of Parkinson's disease. All of the Parkinson's patients received right unilateral electrode placements during ECT. The deliriums all appeared

reversible, but varied in length between 7 days and 3 months after the completion of ECT. Given these findings, it does appear that an ECT-induced delirium occurs more commonly in Parkinson's patients than in patients with cerebrovascular accident (1) or other neurologically healthy, elderly, depressed patients (2, 3).

Since ECT is an effective treatment for both the affective and motor symptoms of Parkinson's disease, further work is needed to identify ways to minimize the encephalopathic side effects of ECT in patients with Parkinson's disease while maintaining the therapeutic advantages of the treatment.

Future studies should examine the potential role that structural brain changes, along with certain clinical and ECT measures, such as electrode placement, ECT medications, frequency of treatment, and the electrical charge, may play in the pathophysiology of ECT-induced delirium (2-4).

GARY S. FIGIEL, M.D.
Atlanta, Ga.

Dr. Oh and Associates Reply

SIR: We were pleased to receive such a robust response to our letter. Drs. Zervas and Fink and Dr. Rudorfer and colleagues raise the question of the possible role of increased L-dopa-generated dopamine activity in the development of delirium in Parkinson patients receiving ECT. In our study, not all patients who experienced post-ECT delirium were taking L-dopa; two of seven patients were not receiving this medication. However, three of the four patients who were free of post-ECT delirium were receiving L-dopa (with carbidopa).

The suggestion that dopamine-active medications be decreased before ECT is appropriate. This has been our standard practice. In fact, our initial approach in treating psychotic Parkinson patients is to decrease anti-Parkinson medications (and other psychoactive drugs) to as low a level as tolerated prior to any other form of treatment.

Dr. Figiel cited two studies consistent with our observations that Parkinson patients experience ECT-induced delirium. In view of the concerns about dopamine-active medications, it is appropriate to point out that the daily dosage of the dopamine agonists administered in those studies tended to be independent of the development of delirium.

ECT-released dopamine should have an extremely short half-life, measured in minutes to hours. Therefore, we question whether ECT-released dopamine could singularly be the cause of delirium persisting for as long as weeks after ECT.

The speculation that an altered blood-brain barrier could be responsible for the delirium is intriguing. Increased passage of L-dopa across this barrier could account for both the delir-

ium and the improvement in Parkinson symptoms. However, one must not lose sight of the fact that carbidopa should also gain access to the central nervous system (CNS) if the blood-brain barrier is damaged. This could offset the effects of increased CNS L-dopa. Carbidopa blocks dopa-decarboxylase, thereby blocking the effects of L-dopa. Normally, it is excluded from the brain by the blood-brain barrier. If there was significant breakdown of the blood-brain barrier, carbidopa passage could lead to marked deterioration of Parkinson control; this was not observed in any of our cases.

Pre-ECT cognitive status may not be a perfect predictor of post-ECT delirium. Prior to ECT, six of our patients underwent formal psychometric testing. Of the three patients with dementia, only two experienced post-ECT delirium. Consequently, other factors such as changes in levels of other neurotransmitters (1), preexisting structural abnormalities (2), and ECT treatment variables may contribute to the development of post-ECT delirium.

Despite the emphasis placed on the delirium that developed in our Parkinson patients, we should not lose sight of the fact that ECT was an effective form of treatment in the majority of our patients. This population of patients presents physicians with difficult treatment dilemmas. We believe that ECT remains an appropriate therapeutic choice in properly selected patients. We concur with Dr. Figiel that further investigations should be directed at the causes of post-ECT delirium to better refine this useful treatment modality.

A Second Look at the Placebo Response

SIR: In a recent letter, Dr. Frederick J. Lichtigfeld and Dr. Mark A. Gillman proposed that an endogenous opioid system may be involved in the placebo response (1). They cited their work in dealing with alcohol withdrawal states.

In fact, in 1978 Levine and associates (2) suggested the possible role of endogenous endorphin release in mediating placebo response. They studied the effect of naloxone, an opiate antagonist, on dental postoperative pain. Under double-blind, randomized conditions, patients were given either naloxone or placebo several hours after extraction of impacted molars. Patients receiving naloxone reported significantly greater pain than those given placebo. Placebo nonresponders had almost the same postoperative pain levels as those receiving naloxone. In addition, naloxone reduced the prior positive response in patients who had initially responded to placebo. They concluded that endorphin release mediated placebo analgesia in their sample of patients.

Placebo responders are often overlooked in experimental studies. Yet a better understanding of the placebo response would allow for therapy to be more targeted. This would help to avoid the use of unnecessary medication and minimize as-

sociated side effects. The response is complicated and seems to involve a number of biological and psychosocial variables (3, 4). Whether a final common pathway involving the opioid system is found remains to be seen. In addition, the mechanism of the placebo response may vary with the behavior or condition being studied. Perhaps a different set of substances is involved when examining antidepressant response and alcohol withdrawal or pain control. The placebo response deserves more intensive study.

MICHAEL R. LAVIN, M.D.
Glen Oaks, N.Y.

Dr. Lichtigfeld and Dr. Gillman Reply

SIR: We thank Dr. Lavin for his comments on our letter. Dr. Lavin cites the work of Levine et al., who suggested the role of the endorphins in mediating placebo responses in 1978 (his reference 2). However, these authors only postulated that the endorphins might mediate one aspect of the placebo effect, namely placebo-induced analgesia. We did not claim priority for their suggestion because we were dealing with another condition, namely the placebo response in alcohol withdrawal, in which we postulated the possibility that the endorphin system might also be involved. From our work we then generalized to states of mood, in which we suggested that the endorphins could be involved in placebo responses related to mood disorders generally.

The possibility mentioned by Dr. Lavin, that all placebo responses might be mediated by a final common pathway via the endorphins, may be a premature assumption. Recent work has implicated the serotonergic system in a study comparing vitamin B₆ and placebo in premenstrual tension syndrome in which both agents were equally effective (1). However, the latter work does not exclude the possibility that the endorphin system is also involved in placebo responses to therapy in this condition (1).

Sociocultural Perspectives on Substance Abuse Disorders

SIR: I wish to express appreciation and concern regarding the article on substance abuse disorders by the Group for

the Advancement of Psychiatry (GAP) Committee on Alcoholism and Addictions (1).

The article provided an excellent summary of medical perspectives on these disorders yet also seemed distressingly deficient with regard to sociocultural perspectives. Moreover, it seemed embedded in, and thereby perpetuates, the prevailing American ethnocentric, sociopolitical economic ideology that unconsciously dominates so much thinking about and response to addiction. As such it epitomized APA President, Lawrence Hartmann's concern, voiced in a recent *APA Monitor*, that "psychiatry as a model of illness and wellness has shrunk back from biopsychosocial integration toward the narrower, physiologic medical model."

To summarize some relevant issues very briefly, it is increasingly clear that there is wide cross-cultural variation in the acceptability and complications of specific drugs. For example, the introduction of alcohol to tribal peoples has proved widely disastrous, whereas psychedelics used in ritual sacred contexts, such as the Native American Church, apparently lead to little abuse and are regarded as sacramental and therapeutic. Important determinants of a drug's acceptability include not only its morbidity and lethality, but also socioeconomic and political factors such as how long a drug has been available in society, how deeply ingrained its use and sale are in the economy, and whether members of the ruling class are addicted to it. Such factors help answer conundrums such as why we currently spend millions of dollars annually to curtail the use of marijuana, which has an extremely low mortality (zero deaths attributed to marijuana use alone in 1985 is the most recent figure I have seen), yet subsidize growers of tobacco, which causes an extremely high mortality.

The omissions in the article are striking. There was no attention given to nicotine addiction even though it claims over 300,000 lives each year in this country alone. Compare this with the 6,000 deaths per year cited in the article for the total number of deaths (in 1980) from *all* illicit drugs combined and it becomes apparent that something in this article and our collective thinking is tragically amiss.

Social, political, and economic factors also determine which etiological factors are emphasized, e.g., poverty or criminality, and whether resources go predominately toward legal intervention, as they do in the United States, or to the medical and mental health communities for treatment.

It is therefore striking that the article failed to discuss in any depth the relationship of addiction to socioeconomic factors. Yet much drug addiction is clearly a function and symptom of such social ills as poverty, deprivation, and alienation. To fail to address these adequately is to fail the poor.

These omissions bring to light another implicit assumption in the article; namely that psychiatry's proper role is almost exclusively the treatment of individual addicts. Obviously this role is crucial. Yet it may be only by additional preventive intervention in the political and educational domains to ameliorate social, economic, and ideological causes that we can hope to be widely effective in the prevention and treatment of substance abuse disorders.

ROGER WALSH, M.D., PH.D.
Irvine, Calif.

Dr. Westermeyer Replies

SIR: Dr. Walsh's comments provide a welcome opportunity for us to elaborate on certain points raised by the paper on substance abuse disorders prepared by the GAP Committee on Alcoholism and Addictions.

Our report was addressed primarily to our colleague-readers in North America, rather than to an international audience. Several of our committee members have had considerable research and consultative experience in Asia, Europe, and Latin America, as well as experience with diverse socioeconomic groups in North America (see works by Blumenthal, Francis, Galanter, Khantzian, Miller, Millman, Nace, Tamerin, Westermeyer). Consequently, we were not unmindful of the sociocultural issues raised by Dr. Walsh, nor are we unconcerned with them. However, we had to select topics that the broad mainstream of our psychiatric colleagues could identify as useful to them in their daily work. There was no effort to cover the entirety of the alcoholism-addictions field in one article.

The issue of tobacco raised by Dr. Walsh is well taken. Certainly, tobacco dependence is a major health threat facing our society. However, its current relevance to many psychiatrists is at issue. *DSM-III-R* criteria for nicotine dependence require advanced pathology along with inability to quit despite medical advice. Nicotine use, abuse, or dependence without a diagnosable condition plus inability to quit after physician recommendation are not diagnosable conditions under *DSM-III-R* criteria. *ICD-9* does not go even as far as *DSM-III-R*. We considered raising these issues regarding nicotine, but a single, focused article was not felt to provide sufficient space to address this important matter in the thorough fashion that it deserves.

We would take issue with Dr. Walsh's innuendo that cannabis abuse and dependence is not a problem in the United States. As clinicians, we regularly see patients whose lives have been adversely affected by cannabis. Clinical surveys over the last two decades have shown that cannabis is second only to alcohol as a substance of abuse in the United States. We would like to see Dr. Walsh's source for the statement "zero deaths attributed to marijuana use alone in 1985." Deaths do occur from suicide, vehicular accidents, other accidents, and homicide in association with cannabis use. Autopsy protocols do not routinely call for cannabis determinations in cases of violent or uncertain death, any more than they require routine nicotine determinations. Were such protocols in place, we might well obtain a clearer picture of cannabis-related problems in the United States. Cannabis-induced fatality in aviation has been documented.

As the newest GAP committee to join that august body, we on the Alcohol Addictions Committee take the charges listed by Dr. Walsh seriously. We do indeed plan to address socioeconomic and sociocultural dimensions of substance-related disorders in our society, including nicotine addiction. By the same token, we believed that in preparing our first report we should begin our quest to influence the minds, hearts, and professional behaviors of our psychiatrist-colleagues by going to those areas of clinical concerns faced daily by them, rather than starting with our concerns, many of which closely match those listed by Dr. Walsh.

JOSEPH WESTERMEYER, M.D., M.P.H., PH.D.

Cocaine Abstinence: "Withdrawal" or Residua of Chronic Intoxication?

SIR: I am pleased to learn that Sally L. Satel, M.D., and colleagues (1) have replicated and expanded our group's find-

ings regarding clinical phenomenology experienced by cocaine addicts during short-term abstinence (2). After reviewing results of both studies, I find that the term "withdrawal" has interfered with our understanding of addiction to stimulants. As noted, our group preferred "short-term abstinence" to "cocaine withdrawal." The issue is conceptual—not just semantic. A traditional sense of "withdrawal" in addicts is probably specific to depressant drugs and is derived from a seminal study by Himmelsbach (3) with opiate addicts and, to a lesser degree, from studies of short-term abstinence syndromes in alcoholics (4). In classic withdrawal, addicts notice *rebound hyperexcitability* (5) during which they experience increased dysphoric psychophysiological phenomena in a matter of hours or days following cessation of a substance. There is a crescendo of distress followed by defervescence of symptoms and signs over days to weeks. In the study of Dr. Satel and colleagues (1) and our study (2), there were linear-like decreases in symptoms over several days with greatest distress noted during use and the immediate postcessation period. In essence, abstinence phenomena reported by our residential subjects were a carryover of *chronic intoxication* effects probably combined with a minimum of conditioned phenomena.

We need to better understand the phenomena of chronic intoxication in addict populations. This would include not only study of neurophysiological effects (i.e., effects of receptor wear and tear as presented by Dr. Satel and colleagues) but also the interplay among adverse medical, legal, social, and occupational consequences and central nervous system changes. In contrast to withdrawal and early abstinence syndromes, periods of chronic intoxication range from months to years. For a frame of reference, one might conceptualize that a course of chronic substance intoxication exists in three phases. The early phase consists of primarily euphoria, few adverse consequences, and establishment of conditioned learning (6). Midphase is the time when there is a decrement in euphoria intensity with continued use of a substance and increased dysphoria secondary to neurophysiological changes and environmental consequences. Late phase consists of minimal euphoria following administration of a substance and growing dysphoria (dopamine depletion?) that becomes intolerable, causing the addict to cease substance use, seek treatment, or accept refuge as a modestly paid residential-research subject. Clinicians are familiar with addicts in the late phase of chronic intoxication who voluntarily seek treatment not because they are in a situational crisis, but because they are "tired."

Hopefully, future research regarding chronic intoxication will help to better understand abstinence phenomena in order to develop interventions more specific to the clinical course of addiction disorders.

Does Light Therapy Present an Ocular Hazard?

SIR: The literature now reports several promising applications of artificial bright light for treatment of winter depression and various circadian rhythm disturbances. A recent letter (1) reported the case of a patient suffering from premenstrual syndrome who was scheduled for such treatment. Light therapy was withheld, however, because ophthalmological tests revealed retinal pathology.

We would like to reinforce the authors' concern. First, one wants to avoid ascribing preexisting retinal pathology to light treatment. Second, protracted use of artificial bright light might exacerbate certain preexisting retinal lesions. Both practical and theoretical implications have been the focus of a recent detailed review (2). Nevertheless, debate continues among light therapists as to whether patients should routinely be prescreened by an ophthalmologist (3).

There should be no lingering doubt that a basic ocular screening (4) is an essential safety precaution. In routine clinical practice, the patient can complete the eye exam externally and submit the chart. The field still needs to elucidate specific contraindications. There is no long-term experience with light treatment, and all conclusions pointing to innocuousness of the procedure (2) have been based on relatively short-term evaluations.

Is there a relation between bright light exposure and retinal pathology? Long-term light exposure may be a factor contributing to normal retinal aging, age-related degenerative diseases, and certain inflammatory responses (5). Light of even moderate intensity can elicit biochemical cascades that generate potent mediators of degenerative and inflammatory cellular responses (6).

Patients with various retinal diseases and pterygium (which is conjunctival) have inquired whether they are suited for light treatment. The diseases have included background diabetic retinopathy, cystic macular edema, lattice degeneration, early stage hypertensive retinopathy, chorioretinal scars, optic nerve head swelling, and pterygium. Many patients with glaucoma have been routinely excluded. Although there is no evidence that diabetic retinopathy is exacerbated by light, its pathogenesis is still only partially understood. Late stages of retinopathy are among the leading causes of blindness in the Western world, and some of the associated inflammatory-like responses might conceivably increase with light exposure. Cystic macular edema has been noted frequently after exposure to sunlight or artificial light sources (5). It is well-known that pterygia occur more frequently in people exposed to high levels of environmental light. It is unknown whether glaucoma is related to light exposure; light-sensitive neuromodulators or neurohormones (melatonin and dopamine), however, may be involved in regulation of intraocular pressure.

With the spreading application of bright light treatment, the number of such anecdotal reports of ocular pathology is

bound to increase. Similarly, preexisting ocular pathology will be falsely attributed to light treatment. If an ophthalmologist evaluates such patients, supervised use of light therapy becomes possible for many who would otherwise be excluded. Ophthalmological screening—which is quite routine—seems to us mandatory. This should be followed by ophthalmological surveillance of light-treated patients with retinal pathology.

New York, N.Y.

An Ethnological Approach to Self-Injurious Behavior

SIR: Ronald M. Winchel, M.D., and Michael Stanley, Ph.D. (1), reviewed the data on self-injurious behavior, with regard to its psychodynamic and biological aspects. They found that self-injurious behavior occurs among mentally retarded individuals, psychotic patients, prison populations, and individuals with severe character disorders. The authors state that “self-injurious behavior is a dramatic but poorly understood phenomenon” and “occurs in a variety of clinical settings, and features of the behavior vary among these settings.”

In their review, the authors did not mention cases of self-mutilating behavior that occurred during ancient Mediterranean “rites.” Indeed, in a recent letter (2), we mentioned Sir James Frazer’s work (3), in which the author describes cult worship of the Great Mother Cybele. This cult required its followers to perform ceremonial genital self-mutilation, in recollection of the mythological experience of Attis. Moreover, during this ceremony, the great minister of the cult would cut the skin of his own arms, as a symbolic repetition of his own previous genital mutilation, and sprinkle his blood over the followers in symbolic communion with the Great Mother.

This pattern of religious behavior suggests a similarity with the case reported by Kafka (4), in which the author suggested that the blood may be linked to his patient’s internalized representation of her mother.

In our view, self-injurious behavior may be considered equivalent to genital self-mutilation and should be conceived as an attempt to return to the mother’s womb in the context of a schizophrenic regression (5).

Indeed, studies in cultural anthropology tend to show that

much of man’s behavior and many of his beliefs as to the proper way to satisfy biological needs depend upon the particular sociocultural and religious “milieu” into which he is born (6). Since the combination of social science and psychoanalytic theories has made important contributions to understanding human behavior, we would like to underline the importance of the ethnologic approach to the poorly understood phenomenon of self-injurious behavior.

P. NOVELLO, M.D.
A. PRIMAVERA, M.D.
Genoa, Italy

Dr. Winchel and Dr. Stanley Reply

SIR: We are grateful to Dr. Novello and Dr. Primavera for raising an interesting aspect of self-mutilation which we chose not to explore in our review, i.e., the role of self-injury in ritual practice. Dr. Novello and Dr. Primavera cite the example of Cybele worship. Multiple examples of ritual self-injury can be found in the cultures of several continents. For readers who are interested in further details regarding the tradition of Cybele and Attis—and for a review of the historical anthropology of self-mutilating behaviors—we recommend Dr. Armando R. Favazza’s excellent book, *Bodies Under Siege* (1).

As Dr. Novello and Dr. Primavera imply, ethnographic variations in psychopathologic behavior should not be overlooked in studies of psychiatric conditions—and too frequently they are. The ethnocentric perspective of many individuals engaged in behavioral research may serve to unintentionally blind us to the variations of behavior that may be found cross-culturally. Awareness of such differences are not only crucial for an empathic understanding of the subjective experience of the patient, but may also serve to highlight certain behavioral features that may merit more detailed attention. Here in the United States, our rich diversity of communities provides us with both the opportunity and responsibility to examine cross-cultural differences.

Despite our agreement with Dr. Novello on this point, in our review we chose not to examine ritual self-injury. In such behavior we considered the locus of motivation to be found, *not* within the individual, but within the group culture. As such, we conclude that despite the topographic similarity of ritual self-injury, it is fundamentally different from the forms of self-injury we did discuss.

Dr. Novello and Dr. Primavera note the similar theme of introjection of the mother found both in the practice of Cybele worship and the speculations of psychodynamic theoreticians regarding the motivation to self-injure. This is an astute ob-

ervation and one that supports the notion that the projective imagery of individuals may be mirrored in the mythic imagery of cultures. But one also wonders, whose imagery is being revealed: that of the patient or that of the psychoanalyst? Despite the heuristic utility of object-relations theory, can its specific symbols—such as merger with the Great Mother—be considered a cult-myth? A deconstructionist examination of object-relations theory may allow us to separate the pure theory from its cultural attributions. As for the ubiquity of Great Mother themes across time and culture—ah, to be Jung again.

Patients' Appearance and Psychopathology

SIR: The recent letter to the Editor by Justin O. Schechter, M.D. (1), raises several issues which deserve comment. Dr. Schechter suggested that "cosmetic characteristics" such as multiple earlobe piercing or tattoos should not be linked to psychiatric diagnosis. He further described such correlations as "dangerous," a conclusion which seems harsh.

Better observation of patients needs to be encouraged. The initial aspects of the mental status examination involve a general description of the patient (2). This includes details of facial expression, eye contact, personal cleanliness, habits of dress, and motor activity. While this part of the examination is the most straightforward and involves the least interpretation, it seems to be frequently overlooked and inadequately documented. In general, clinicians tend to focus on the more

"positive" or dramatic symptoms of illness such as delusions, hallucinations, or compulsive behaviors. This may lead to the lack of recognition of more subtle pathology such as neuroleptic-induced akathisia or akinesia. It also tends to negate the large influence that appearances play in the rapport of the doctor-patient relationship.

There has been one study of the "tinted-spectacles" sign in which patients who wore sunglasses in the general medical hospital were found to be more likely to display psychopathology (3). Further analysis does suggest that like other signs in psychiatry, the list of possible differential diagnoses is a long one (4). In at least one schizophrenic man, the onset of persistent use of sunglasses was helpful in timing the start of his recent exacerbation. What is important though is that unusual appearances or behaviors be recorded and later questioned taking into account the context in which they appeared.

These observations may not only prove useful in diagnosis, but provide clues to help gauge the progress of treatment. Another patient was noted to no longer cover his ears once his auditory hallucinations had started to subside. While the lack of pathognomonic signs and symptoms is frustrating, better observations will most certainly lead to more definitive treatments.

Annual Index

Following is the comprehensive index for volume 149 of the *Journal*, which covers all material in January 1992 through December 1992. The complete citation for each article in the author index is listed under the name of the first author. Coauthors are listed alphabetically with a cross-reference to the first author; cross-references containing multiple first author names separated by semicolons indicate multiple articles by the coauthor. Book reviews appear in the author index under the name of the reviewer and in the subject index under the heading Books Reviewed; the books reviewed are arranged alphabetically by the surname of the book's first author or editor. In addition to being indexed by author name, letters to the Editor regarding articles published in 1992 are indicated in parentheses after the citations for those articles.

Each entry in the subject index is identified by the surname of the first author only; commas between names of authors of letters to the Editor indicate multiple letters. Two-letter abbreviations are used for months. Entries other than Special Articles, Regular Articles, Commentaries, and Clinical and Research Reports are given the following designations: editorial (editorial), In Memoriam (in mem), book review (bk rev), letter to the Editor (letter), and Official Actions (off acts). Corrections are cited with the articles to which they refer and under the heading Corrections in the subject index.

Subject Index

A

Abortion

- APA actions on reproductive rights (off acts). American Psychiatric Association Committee on Women, My 723
- Sequelae of denied abortion (letter). Storch, Fe 275

Academic Psychiatry

- Does the end justify the means (letter). Khouzam, Je 845-846

Achievement

- Differences in neuropsychological and academic achievement between adolescent delinquents and status offenders. Famularo, Se 1252-1257

Acquired Immune Deficiency Syndrome see AIDS

Addiction

- Position statement on the care of pregnant and newly delivered women addicts (off acts). American Psychiatric Association Committee on Women, My 724

Admissions

- Historical perspective on the role of state hospitals viewed from the era of the "revolving door." Geller, No 1526-1533

Adolescents

- Credibility of patients in psychiatric research (letter). Powell, reply of Sanders, Au 1126-1127
- Depressive illness among chemically dependent adolescents. Deykin, Oc 1341-1347
- Dexamethasone suppression test in adolescent outpatients with major depressive disorder. Birmaher, Au 1040-1045
- Differences in neuropsychological and academic achievement between adolescent delinquents and status offenders. Famularo, Se 1252-1257
- Dissociation and suicide in the young (letter). Jensen, reply of Hendin, Ap 578-579
- Note on racial bias in the admission of children and adolescents to state mental health facilities versus correctional facilities in New York. Kaplan, Je 768-772
- Panic disorder in children and adolescents: a review. Moreau, Oc 1306-1314
- Predicting substance use in late adolescence: results from the Ontario Child Health Study follow-up. Boyle, Je 761-767
- Pubertal stage and panic attack history in sixth- and seventh-grade girls. Hayward, Se 1239-1243
- Relationship between adolescent suicidal behavior and life events in childhood and adolescence. de Wilde, Ja 45-51
- Suicidality and the young (letter). White, reply of Hendin, Je 849-850
- Adrenergic Blockers**
- Randomized, double-blind, crossover, placebo-controlled comparison of propranolol and betaxolol in the treatment of neuroleptic-induced akathisia. Dumon, My 647-650
- Adrenergic Receptors**
- Adrenergic receptor genes as candidate genes for panic disorder: a linkage study. Wang, Ap 470-474

Affective Disorders see also Depression; Mania; Seasonal Affective Disorder

- Abnormal intracellular calcium ion concentration in platelets and lymphocytes of bipolar patients. Dubovsky, Ja 118-120
- Are schizophrenia and affective disorder related? a selective literature review. Taylor, Ja 22-32
- Assessment of lineality in bipolar I linkage studies. Simpson, De 1660-1665
- Blunting of clonidine-stimulated growth hormone release in mania (letter). Anseau, Ap 584
- Change in ideational content as a prodromal symptom in affective disorders (letter). Badal, reply of Fava, Mr 427-428
- Childhood factors in adult self-destructive behavior (letter). Paris, reply of van der Kolk, Se 1280-1281
- Comorbidity in mania at first hospitalization. Strakowski, Ap 554-556
- Contested boundaries of bipolar disorder and the limits of categorical diagnosis in psychiatry. Blacker, No 1473-1483
- DSM-III-R impulse control disorders not elsewhere classified: clinical characteristics and relationship to other psychiatric disorders. McElroy, Mr 318-327
- Flunarizine as maintenance treatment of a patient with bipolar disorder (letter). Lindelius, Ja 139
- Gender differences in comorbid anxiety and mood disorders (letter). Ochoa, Oc 1409-1410
- Initial findings on preventive intervention for families with parental affective disorders. Beardslee, Oc 1335-1340
- Lack of association between dopamine D₁ and D₂ receptor genes and bipolar affective disorder. Nöthen, Fe 199-201
- Lithium, benzodiazepines, and sexual function in bipolar patients. Ghadirian, Je 801-805
- Lithium-discontinuation-induced refractoriness: preliminary observations. Post, De 1727-1729
- Lithium treatment of a bipolar patient with cystic fibrosis (letter). Turkel, Ap 574
- Mania compared with unipolar depression in old age. Shulman, Mr 341-345
- Mania in late life: focus on age at onset. Young, Jy 867-876
- Nicotine cessation, mania, and depression (letter). Labbate, My 708 (correction: Se 1287)
- Nicotine withdrawal symptoms and psychiatric disorders: findings from an epidemiologic study of young adults. Breslau, Ap 464-469
- Reliability of best-estimate diagnosis in genetic linkage studies of major psychoses: results from the Quebec pedigree studies. Maziade, De 1674-1686
- Schizoaffective disorder and affective disorders with mood-incongruent psychotic features: keep separate or combine? evidence from a family study. Maier, De 1666-1673
- Transduction of psychosocial stress into the neurobiology of recurrent affective disorder. Post, Au 999-1010

- Treatment of imipramine-resistant recurrent depression, IV: a double-blind crossover study of tranylcypromine for anergic bipolar depression. Thase, Fe 195-198

Africa

- Panic disorder in Benin, West Africa (letter). Bertschy, Oc 1410

Aggression see Violence

Aging see Geriatric Psychiatry

Agitation

- Agitation and postdexamethasone cortisol levels in Alzheimer's disease. Lawlor, Ap 546-548

Agoraphobia

- Alprazolam plasma concentrations and treatment response in panic disorder and agoraphobia. Lesser, No 1556-1562

- Latent structure of anxiety symptoms in anxiety disorders. Kenardy, Au 1058-1061

- Onset of panic disorder. Faravelli, Je 827-828

- Protective effects of imipramine maintenance treatment in panic disorder with agoraphobia. Mavissakalian, Au 1053-1057

AIDS see also Human Immunodeficiency Virus

- AIDS/HIV risk behavior among the chronically mentally ill. Kelly, Jy 886-889

- AIDS policy: guidelines for inpatient psychiatric units (off acts). American Psychiatric Association Commission on AIDS, My 722

- AIDS policy: guidelines for outpatient psychiatric services (off acts). American Psychiatric Association Commission on AIDS, My 721

- Bereavement reactions among homosexual men experiencing multiple losses in the AIDS epidemic. Neugebauer, Oc 1374-1379

- Coping with the threat of AIDS: the role of social support. Leserman, No 1514-1520

- Mania and AIDS (letters). Holmes, Whitefield, reply of Kiebertz, Ap 583-584

- Mania in AIDS and syphilis (paresis) (letter). Rosenbaum, Mr 416

- Pharmacotherapy and psychotherapy for major depression in a man with AIDS (letter). Sullivan, Ja 138

Akathisia

- Randomized, double-blind, crossover, placebo-controlled comparison of propranolol and betaxolol in the treatment of neuroleptic-induced akathisia. Dumon, My 647-650

Alaska

- Prevalence of seasonal affective disorder in Alaska. Booker, Se 1176-1182

Alcohol and Alcoholism

- Alcohol abuse, depression, and suicidal behavior in schizophrenia. Bartels, Mr 394-395

- Decreased brain metabolism in neurologically intact healthy alcoholics. Volkow, Au 1016-1022

- Depressive illness among chemically dependent adolescents. Deykin, Oc 1341-1347

- Major depression or alcohol-induced organic affective syndrome? (letter). Hersh, reply of Cusack, Se 1276

- Meta-analysis of subjective sensitivity to alcohol in sons of alcoholics. Pollock, No 1534-1538

- Past substance abuse and clinical course of schizophrenia. Zisook, Ap 552-553
- Position statement on the care of pregnant and newly delivered women addicts (off acts). American Psychiatric Association Committee on Women, My 724
- Posttraumatic stress disorder among substance users from the general population. Cottler, My 664-670
- Predicting substance use in late adolescence: results from the Ontario Child Health Study follow-up. Boyle, Je 761-767
- Alexithymia**
- Alexithymia and the ECA study (letter). Lesser, reply of Simon, Se 1281-1282
- Alprazolam**
- Alprazolam as a neuroleptic adjunct in the emergency treatment of schizophrenia. Barbee, Ap 506-510 (correction: Au 1129)
- Alprazolam plasma concentrations and treatment response in panic disorder and agoraphobia. Lesser, No 1556-1562
- Alzheimer's Disease see also Dementia**
- Agitation and postdexamethasone cortisol levels in Alzheimer's disease. Lawlor, Ap 546-548
- Antiglucocorticoid effects of DHEA-S in Alzheimer's disease (letter). Leblhuber, reply of Wolkowitz, Au 1125-1126 (correction: No 1622)
- Are there clinical differences between familial and nonfamilial Alzheimer's disease? Luchins, Au 1023-1027
- Bright light treatment of behavioral and sleep disturbances in patients with Alzheimer's disease. Satlin, Au 1028-1032
- Cognitive deficits of patients with Alzheimer's disease with and without delusions. Jeste, Fe 184-189
- Empirical evaluation of the Global Deterioration Scale for staging Alzheimer's disease. Eisdorfer, Fe 190-194 (correction: Au 1129)
- Glutamate and other CSF amino acids in Alzheimer's disease. Pomara, Fe 251-254
- High-intensity signals in Alzheimer's disease without cerebrovascular risk factors: a magnetic resonance imaging evaluation. Kumar, Fe 248-250
- Impact of psychiatric hospitalization on behavioral complications of Alzheimer's disease. Zubenko, No 1484-1491

- Anxiety**
- Anxiety disorders and Parkinson's disease (letter). Iruela, reply of Stein, My 719-720
- Anxiety syndromes as epiphenomena of primary major depression: outcome and familial psychopathology. Coryell, Ja 100-107
- Comorbidity of parental anxiety disorders as risk for childhood-onset anxiety in inhibited children. Rosenbaum, Ap 475-481
- Effectiveness of a meditation-based stress reduction program in the treatment of anxiety disorders. Kabat-Zinn, Jy 936-943
- Gender differences in comorbid anxiety and mood disorders (letter). Ochoa, Oc 1409-1410
- High cholesterol levels in patients with panic disorder. Bajwa, Mr 376-378
- Latent structure of anxiety symptoms in anxiety disorders. Kenardy, Au 1058-1061
- Panic disorder in children and adolescents: a review. Moreau, Oc 1306-1314
- Performance anxiety (letter). Chanel, reply of Clark, Fe 278-279
- Psychodynamic psychiatry in the "decade of the brain." Gabbard, Au 991-998
- Treatment of generalized anxiety disorder and trichotillomania with buspirone (letter). Reid, Ap 573-574

Appetite

Regulation of appetite and cholecystokinin secretion in anorexia nervosa. Geraciotti, Jy 958-961

Asians

Cross-cultural differences in rating hyperactive-disruptive behaviors in children. Mann, No 1539-1542

Assay Techniques

Comparison of fluorescent polarization immunoassay and radioimmunoassay in measuring cortisol levels in prepubertal depressed children. Weller, Oc 1395-1396

Athletes

Overview of sport psychiatry. Begel, My 606-614

Atropine

Intravenous versus intramuscular atropine in ECT. Kramer, Se 1258-1260

Attention Deficit Hyperactivity Disorder

Comorbidity of attention deficit hyperactivity disorder and other disorders (letters). Bellak, Huessy, Boon, Huttenbach, Anderson, reply of Biederman, Ja 147-149

Cross-cultural differences in rating hyperactive-disruptive behaviors in children. Mann, No 1539-1542

Autism

Autism syndrome as a final common pathway of behavioral expression for many organic disorders (letter). Darby, reply of Ritvo, Ja 146-147

Differential response of seven subjects with autistic disorder to clomipramine and desipramine. Gordon, Mr 363-366

Fluoxetine and serotonin in autism (letter). Rickards, Je 851

Magnetic resonance imaging of the posterior fossa in autistic adults. Garber, Fe 245-247

Regional cerebral blood flow in childhood autism: a SPECT study. Zilbovicius, Jy 924-930

Axis I Conditions

Relationship between personality and DSM-III axis I disorders in the population: results from an epidemiological survey. Nestadt, Se 1228-1233

B

Bash v Board of Medical Practice

Protecting patients from clinician-patient sexual contact (letter). Bursztajn, Se 1276

Battered Woman Syndrome

Battered woman syndrome (letter). Blumberg, My 714-715

Behavior Disturbances

Brief anabolic steroid use and sustained behavioral reaction (letter). Dalby, Fe 271-272 (letter: Moss, No 1616)

Impact of psychiatric hospitalization on behavioral complications of Alzheimer's disease. Zubenko, No 1484-1491

Steroid use and aggression (letter). Moss, reply of Dalby, No 1616

Pharmacotherapy of agitation in dementia (letter). Herz, reply of Coccaro, De 1757-1758

Behavior Therapy

Alcohol and addictions (letter). Hughes, reply of Khantzian, Au 1118-1119

Performance anxiety (letter). Chaneil, reply of Clark, Fe 278-279

Pharmacologic and cognitive-behavioral

treatment for bulimia nervosa: a controlled comparison. Agras, Ja 82-87

Relapse after cognitive behavior therapy of depression: potential implications for longer courses of treatment. Thase, Au 1046-1052

Technique for training schizophrenic patients in illness self-management: a controlled trial. Eckman, No 1549-1555

Benzodiazepines see also specific drugs

GABA-benzodiazepine receptors (letter). Wamsley, reply of Zorumski, Ap 582-583

Lithium, benzodiazepines, and sexual function in bipolar patients. Ghadirian, Je 801-805

Response of schizophrenic patients to benzodiazepines (letter). Dreher, reply of Wolowitz, Mr 421-422

Benzotropine

Sinus bradycardia related to the use of benzotropine mesylate (letter). Voinov, My 711

Bereavement

Bereavement reactions among homosexual men experiencing multiple losses in the AIDS epidemic. Neugebauer, Oc 1374-1379

Correlates of persistent depressive symptoms in widows. Nuss, Mr 346-351

Depression after the death of a spouse (letter). Horowitz, reply of Zisook, Ap 579-580

Psychoanalytic conceptualization of perinatal loss: a multidimensional model. Leon, No 1464-1472

Betaxolol

Randomized, double-blind, crossover, placebo-controlled comparison of propranolol and betaxolol in the treatment of neuroleptic-induced akathisia. Dumon, My 647-650

Bias

Note on racial bias in the admission of children and adolescents to state mental health facilities versus correctional facilities in New York. Kaplan, Je 768-772

Racial/ethnic identity and amount and type of psychiatric treatment. Flaskerud, Mr 379-384

Biological Rhythms

Identification of mood variance in depression (letter). Cowdry, reply of Hall, Au 1121-1122

Seven-day mood cycles (letter). Pies, reply of Hall, Mr 418-419

Biopsychosocial Perspective

Clinical problem solving and the biopsychosocial model. Sadler, Oc 1315-1323

Defining the future in medical education (editorial). Pardes, Oc 1293-1294

Need for integrating environmental and biological factors in psychiatry (letter). Strauss, Ja 147

Presidential address: reflections on humane values and biopsychosocial integration. Hartmann, Se 1135-1141

Psychodynamic psychiatry in the "decade of the brain." Gabbard, Au 991-998

Search: body, mind, and human purpose. Freedman, Jy 858-866

Bipolar Illness see Affective Disorders

Blacks

Panic disorder in Benin, West Africa (letter). Bertschy, Oc 1410

Bleeding

Bleeding, a side effect of fluoxetine (letter). Aranth, Mr 412

Blood

Blood groups in panic disorder (letter). Emmanuel, Mr 410

Blood Flow see Cerebral Blood Flow

Blood Levels

Abnormal intracellular calcium ion concentration in platelets and lymphocytes of bipolar patients. Dubovsky, Ja 118-120

Alprazolam plasma concentrations and treatment response in panic disorder and agoraphobia. Lesser, No 1556-1562

Blood levels and acute response to bupropion. Goodnick, Mr 399-400

Clozapine concentrations and clinical response in schizophrenic patients (letter). Owen, reply of Arndt, Au 1120-1121

Elevated cortisol concentrations and the diminished prolactin response to fenfluramine (letter). Mitchell, reply of Dinan, Je 851-852

Haloperidol plasma levels and clinical response: a therapeutic window relationship. Van Putten, Ap 500-505

Serotonin function in depression: effects of seasonality? (letter). Brewerton, reply of Price, Se 1277

Body Dysmorphic Disorder

Acute exacerbation of body dysmorphic disorder during tryptophan depletion (letter). Barr, Oc 1406-1407

Body dysmorphic disorder (letter). Myers, Castelnovo-Tedesco, reply of Phillips, My 718-719

Body dysmorphic disorder: a controlled study of patients requesting cosmetic rhinoplasty (letter). Jerome, reply of Phillips, Ap 577-578

Obsessive-compulsive disorder in relation to body dysmorphic disorder (letter). Tanquary, reply of Phillips, Se 1283-1284

Bone Mineral Density

Bone loss in patients with anorexia nervosa (letter). Hay, Mr 415-416

Book Reviews

Final Exit as a manual for suicide (letter). Sacks, Je 842

Freud and homosexuality (letter). Isay, reply of Stone, Je 847

Major depression or alcohol-induced organic affective syndrome? (letter). Hersh, reply of Cusack, Se 1276

Update of review of guides for patients (letter). Jefferson, Mr 430

Books Reviewed

 Initial findings on preventive intervention for families with parental affective disorders. Beardslee, Oc 1335-1340
 Is childhood sexual abuse a risk factor for bulimia nervosa? Pope, Ap 455-463
 Note on racial bias in the admission of children and adolescents to state mental health facilities versus correctional facilities in New York. Kaplan, Je 768-772
 Panic disorder in children and adolescents: a review. Moreau, Oc 1306-1314
 Physical and sexual abuse histories among children with borderline personality disorder. Goldman, De 1723-1726
 Psychotic symptoms and suicidal behavior in hospitalized children. Livingston, No 1585-1586
 Regional cerebral blood flow in childhood autism: a SPECT study. Zilbovicius, Jy 924-930
 Relationship between adolescent suicidal behavior and life events in childhood and adolescence. de Wilde, Ja 45-51
 Tics and Tourette's disorder: a 2- to 7-year follow-up of 54 obsessive-compulsive children. Leonard, Se 1244-1251
- China**
 Prevalence of tardive dyskinesia, tardive dystonia, and respiratory dyskinesia among Chinese psychiatric patients in Hong Kong. Chiu, Au 1081-1085
- Cholecystokinin**
 CSF cholecystokinin concentrations in patients with panic disorder and in normal comparison subjects. Lydiard, My 691-693
 Regulation of appetite and cholecystokinin secretion in anorexia nervosa. Geraciotti, Jy 958-961
 Replication of action of cholecystokinin tetrapeptide in panic disorder: clinical and behavioral findings. Bradwejn, Jy 962-964
- Cholesterol**
 High cholesterol levels in patients with panic disorder. Bajwa, Mr 376-378
- Chronically Ill Patients**
 Psychosocial rehabilitation and psychiatry in the care of long-term patients. Bachrach, No 1455-1463
- Classification** see **Diagnosis and Classification**
- Cleveland Criteria**
 Evaluation of the Cleveland criteria for inpatient treatment of substance abuse. McKay, Se 1212-1218
- Clomipramine**
 Clomipramine and a case of exhibitionism (letter). Wawrose, Je 843
 Differential response of seven subjects with autistic disorder to clomipramine and desipramine. Gordon, Mr 363-366
 Ineffectiveness of clomipramine for obsessive-compulsive symptoms in a patient with schizophrenia (letter). Bark, Ja 136-137
 Neuroendocrine effects of intravenous clomipramine in depressed patients and healthy subjects. Golden, Se 1168-1175
 Response of obsessive-compulsive disorder and trichotillomania to serotonin reuptake blockers (letter). Graae, Ja 149-150
 Serotonin syndrome (letter). Lejoyeux, Oc 1410-1411
 Treatment of pathological gambling with clomipramine (letter). Hollander, My 710-711
 Trichotillomania treated with clomipramine and a topical steroid (letter). Black, Je 842-843
- Clonidine**
 Blunting of clonidine-stimulated growth hormone release in mania (letter). Ansseau, Ap 584
- Clozapine**
 Acute pancreatitis associated with clozapine use (letter). Martin, My 714
 Addition of fluoxetine to clozapine (letter). Cassidy, Se 1274 (correction: No 1622)
 Clozapine concentrations and clinical response in schizophrenic patients (letter). Owen, reply of Arndt, Au 1120-1121
 Clozapine-induced priapism (letter). Ziegler, Fe 272-273 (correction: Au 1129)
 Clozapine-induced weight gain: prevalence and clinical relevance. Leadbetter, Ja 68-72
 Development of transient obsessive-compulsive symptoms during treatment with clozapine (letter). Patil, Fe 272
 Polyserositis associated with clozapine treatment (letter). Daly, Se 1274-1275
 Possible clozapine exacerbation of bulimia nervosa (letter). Brewerton, Oc 1408-1409
 Seizure with low doses of clozapine (letter). Thomas, Ja 138 (letter: More, Oc 1413)
 Weight gain among schizophrenic patients treated with clozapine. Lamberti, My 689-690
- CNS**
 Autism syndrome as a final common pathway of behavioral expression for many organic disorders (letter). Darby, reply of Ritvo, Ja 146-147
 G proteins: implications for psychiatry. Manji, Je 746-760
- Cocaine**
 Cocaine abstinence: "withdrawal" or residua of chronic intoxication? (letter). Weddington, De 1761-1762
 Crack/cocaine abusers in the general hospital: assessment and initiation of care. Galanter, Je 810-815
 Prevalence of cocaine use among residents of New York City who committed suicide during a one-year period. Marzuk, Mr 371-375
 Severity of cocaine dependence as a predictor of relapse to cocaine use. Weiss, No 1595-1596
 Use of cocaine to prevent opiate withdrawal (letter). Rosen, No 1609
- Cognition** see also **Brain Disorders**
 Antiglucocorticoid effects of DHEA-S in Alzheimer's disease (letter). Leblhuber, reply of Wolkowitz, Au 1125-1126 (correction: No 1622)
 Cognitive deficits of patients with Alzheimer's disease with and without delusions. Jeste, Fe 184-189
 Cognitive impairment in dramatic personality disorders (letter). Burgess, Ja 136
 Influence of topography on the cognitive and psychopathological effects of tardive dyskinesia. Brown, Oc 1385-1389
 Neuropsychological functioning of first-episode schizophreniform patients. Hoff, Jy 898-903
- Cognitive Therapy**
 Crossover study of focused cognitive therapy for panic disorder. Beck, Je 778-783
 Dynamic cognitive therapy anyone? (letter). Larson, Jy 990
 Performance anxiety (letter). Chanel, reply of Clark, Fe 278-279
 Pharmacologic and cognitive-behavioral treatment for bulimia nervosa: a controlled comparison. Agras, Ja 82-87
 Relapse after cognitive behavior therapy of depression: potential implications for longer courses of treatment. Thase, Au 1046-1052
 Technique for training schizophrenic patients in illness self-management: a controlled trial. Eckman, No 1549-1555
- Combat**
 Elderly Israeli Holocaust survivors during the Persian Gulf War: a study of psychological distress. Solomon, De 1707-1710
 Exposure to atrocities and severity of chronic posttraumatic stress disorder in Vietnam combat veterans. Yehuda, Mr 333-336
 Phenomenology and course of psychiatric disorders associated with combat-related posttraumatic stress disorder. Mellman, No 1568-1574
 Symptom responses of female Vietnam veterans to Operation Desert Storm. Wolfe, My 676-679 (correction: Au 1129)
- Combined Drug Therapy** see **Drug Combinations**

Borderline personality disorder and depression (letter). Liebowitz, reply of Gunderson, Ap 581

Borderline personality disorder and depressive disorder (letter). Heritch, Je 852

Combined pharmacotherapy and psychotherapy in the acute and continuation treatment of elderly patients with recurrent major depression: a preliminary report. Reynolds, De 1687-1692

Comparison of fluorescent polarization immunoassay and radioimmunoassay in measuring cortisol levels in prepubertal depressed children. Weller, Oc 1395-1396

Correlates of persistent depressive symptoms in widows. Nuss, Mr 346-351

Depression after the death of a spouse (letter). Horowitz, reply of Zisook, Ap 579-580

Depression and Parkinson's disease: a review. Cummings, Ap 443-454

Depression in borderline patients who split (letter). Muller, Ap 580-581

Depression in patients with acute traumatic brain injury. Fedoroff, Jy 918-923

Depressive illness among chemically dependent adolescents. Deykin, Oc 1341-1347

Dexamethasone suppression test in adolescent outpatients with major depressive disorder. Birmaher, Au 1040-1045

Differences in the effects of divorce on major depression in men and women. Bruce, Jy 914-917

Elevated cortisol concentrations and the diminished prolactin response to fenfluramine (letter). Mitchell, reply of Dinan, Je 851-852

Identification of mood variance in depression (letter). Cowdry, reply of Hall, Au 1121-1122

Is sleep deprivation useful in the treatment of depression? Leibenluft, Fe 159-168

Learned helplessness and urinary MHPG levels in unipolar depression. Samson, Je 806-809

Magnetic resonance imaging in the diagnosis of dementia (letter). Dentino, reply of Rabins, Mr 419

Mania compared with unipolar depression in old age. Shulman, Mr 341-345

Monozygotic mirror-image twin pair with discordant psychiatric illnesses: a neuropsychiatric and neurodevelopmental evaluation. Lohr, Au 1091-1095

Neuroendocrine effects of intravenous clomipramine in depressed patients and healthy subjects. Golden, Se 1168-1175

Pattern of recurrence of illness after recovery from an episode of major depression: a prospective study. Maj, Je 795-800

Prevalence of depressive symptoms among white and African-American caregivers of demented patients (letter). Mintzer, Ap 575-576

Recovery and major depression: factors associated with twelve-month outcome. Keitner, Ja 93-99 (letter: Bennett, Au 1127-1128)

Recovery and relapse from major depressive disorder in the elderly. Hinrichsen, No 1575-1579

Religious coping and depression among elderly, hospitalized medically ill men. Koenig, De 1693-1700

Serotonin function in depression: effects of seasonality? (letter). Brewerton, reply of Price, Se 1277

Seven-day mood cycles (letter). Pies, reply of Hall, Mr 418-419

Update on the dementia spectrum of depression. Emery, Mr 305-317

Depression—Treatment of

Blood levels and acute response to bupropion. Goodnick, Mr 399-400

Bupropion-induced carbohydrate craving and weight gain (letter). Workman, Oc 1407-1408

Can mildly depressed outpatients with atypical depression benefit from antidepressants? Stewart, My 615-619

Cognitive impairment after ECT in patients with parkinson's disease and psychiatric illness (letter). Oh, Fe 271 (letters: Zervas, Rudorfer, Figiel, De 1758-1759)

Control of depression with fluoxetine and antiseizure medication in a brain-injured patient (letter). Wroblewski, Fe 273

Effect of sleep deprivation on brain metabolism of depressed patients. Wu, Ap 538-543

Flunarizine as maintenance treatment of a patient with bipolar disorder (letter). Lindelius, Ja 139

Fluoxetine, suicidal ideation, and aggressive behavior (letter). Selzer, My 708-709

Is sleep deprivation useful in the treatment of depression? Leibenluft, Fe 159-168

Meaning of refractory depression (letters). Black, Storch, reply of Guscott, Fe 277-278

Media coverage versus fluoxetine as the cause of suicidal ideation (letter). Ioannou, Ap 572

Melancholic/endogenous depression and response to somatic treatment and placebo. Peselow, Oc 1324-1334

Oral caffeine augmentation of ECT (letter). Ancill, Ja 137 (letter: Jaffe, No 1610)

Oral versus intravenous caffeine augmentation of ECT (letter). Jaffe, reply of Ancill, No 1610

Penile anesthesia and fluoxetine (letter). Measom, My 709

Pharmacotherapy and psychotherapy for major depression in a man with AIDS (letter). Sullivan, Ja 138

Recovery from protracted depression in old age (letter). Cole, No 1609

Relapse after cognitive behavior therapy of depression: potential implications for longer courses of treatment. Thase, Au 1046-1052

Serotonin syndrome (letter). Lejoyeux, Oc 1410-1411

Treatment of imipramine-resistant recurrent depression, IV: a double-blind crossover study of tranylcypromine for anergic bipolar depression. Thase, Fe 195-198

Visual hallucinations after combining fluoxetine and dextromethorphan (letter). Achamallah, Oc 1406

Phenelzine treatment of depression in Parkinson's disease (letter). Hargrave, De 1751-1752

Desipramine

Blunting growth hormone release in mania (letter). Coupland, reply of Dinan, Se 1286-1287

Differential response of seven subjects with autistic disorder to clomipramine and desipramine. Gordon, Mr 363-366

Pharmacologic and cognitive-behavioral treatment for bulimia nervosa: a controlled comparison. Agras, Ja 82-87

Dexamethasone Suppression Test

Comparison of fluorescent polarization immunoassay and radioimmunoassay in meas-

- uring cortisol levels in prepubertal depressed children. Weller, Oc 1395-1396
- Dexamethasone suppression test in adolescent outpatients with major depressive disorder. Birmaher, Au 1040-1045

Conservatorship for gravely disabled psychiatric patients: a four-year follow-up study. Lamb, Jy 909-913
Crack/cocaine abusers in the general hospital: assessment and initiation of care. Galanter, Je 810-815
Evaluation of the Cleveland criteria for inpatient treatment of substance abuse. McKay, Se 1212-1218
Historical perspective on the role of state hospitals viewed from the era of the "revolving door." Geller, No 1526-1533
Note on racial bias in the admission of children and adolescents to state mental health facilities versus correctional facilities in New York. Kaplan, Je 768-772
Patients who use drugs during inpatient substance abuse treatment. Greenfield, Fe 235-239
- Predicting feasibility of day treatment for unselected patients referred for inpatient psychiatric treatment: results of a randomized trial. Kluiters, Se 1199-1205
Relationship between community resources and state hospital recidivism. Fisher, Mr 385-390
Undetected HIV infection among acutely ill psychiatric inpatients. Sacks, Ap 544-545
Utilization of neuropsychiatric diagnostic tests for general hospital patients with mental disorders. Olsson, De 1711-1717
- Hospitalization**
Impact of psychiatric hospitalization on behavioral complications of Alzheimer's disease. Zubenko, No 1484-1491
Predicting feasibility of day treatment for unselected patients referred for inpatient psychiatric treatment: results of a randomized trial. Kluiters, Se 1199-1205
Religious coping and depression among elderly, hospitalized medically ill men. Koenig, De 1693-1700
Role of violence in decisions about hospitalization from the psychiatric emergency room. McNiel, Fe 207-212
- Hospitalization, Involuntary, see Commitment, Civil**
- Human Growth Hormone**
Blunting growth hormone release in mania (letter). Coupland, reply of Dinan, Se 1286-1287
Blunting of clonidine-stimulated growth hormone release in mania (letter). Anseau, Ap 584
- Human Immunodeficiency Virus**
AIDS/HIV risk behavior among the chronic mentally ill. Kelly, Jy 886-889
Coping with the threat of AIDS: the role of social support. Leserman, No 1514-1520
Fatigue, sleep disturbance, disability, and indices of progression of HIV infection. Darko, Ap 514-520
Neurobehavioral functioning in a nonfounded group of asymptomatic HIV-seropositive homosexual men. Stern, Au 1099-1102
Serum prolactin levels in homosexual and bisexual men with HIV infection. Gorman, Mr 367-370
Stress and HIV infection (letter). Perry, reply of Kessler, Mr 416-417
Undetected HIV infection among acutely ill psychiatric inpatients. Sacks, Ap 544-545
- Hyperactivity**
Cross-cultural differences in rating hyperactive-disruptive behaviors in children. Mann, No 1539-1542
- Hyperventilation**
Hyperventilation-induced cerebral ischemia in panic disorder and effect of nimodipine. Gibbs, No 1589-1591
- Hypnosis**
Psychopathology, hypnotizability, and dissociation. Frischholz, No 1521-1525
- Hypomania see Mania**
- Hyponatremia**
Correction rate of severe hyponatremia and central pontine myelinolysis (letter). Muller, My 715-716
- Hypothalamic-Pituitary-Adrenal Axis**
Hypothalamic-pituitary-adrenal axis hyperactivity and psychosis: recovery during an 8-year follow-up. Coryell, Au 1033-1039
- Hysterectomy**
Hysterectomy in patients with panic disorder (letter). Swales, Je 846-847
- I**
- ICD-10 see Diagnosis and Classification**
- Imipramine**
Imipramine and suicidal thoughts (letter). Hardoby, Mr 412-413
Protective effects of imipramine maintenance treatment in panic disorder with agoraphobia. Mavissakalian, Au 1053-1057
Treatment of imipramine-resistant recurrent depression, IV: a double-blind crossover study of tranylcypromine for anergic bipolar depression. Thase, Fe 195-198
- Impulse Control Disorders**
DSM-III-R impulse control disorders not elsewhere classified: clinical characteristics and relationship to other psychiatric disorders. McElroy, Mr 318-327
- Incest see Child Abuse; Sexual Abuse**
- Injury see also Self-Injurious Behavior**
Depression in patients with acute traumatic brain injury. Fedoroff, Jy 918-923
- Inpatients see Hospital Psychiatry**
- Insanity Defense**
Monitored conditional release of persons found not guilty by reason of insanity (letter). Vartiainen, Mr 415
- Insomnia**
Long-term study of the sleep of insomnia patients with sleep state misperception and other insomnia patients. Salin-Pascual, Jy 904-908
- Insurance**
Judicial and legislative responses to cost containment. Sederer, Se 1157-1161
- Interviewing**
Sensitivity of psychiatric diagnosis based on the best estimate procedure. Kosten, Se 1225-1227
- Israel**
Elderly Israeli Holocaust survivors during the Persian Gulf War: a study of psychological distress. Solomon, De 1707-1710
- J**
- Journals, Psychiatric**
Associations between dimensions of religious commitment and mental health reported in the *American Journal of Psychiatry* and *Archives of General Psychiatry*: 1978-1989. Larson, Ap 557-559
- Jungian Psychology**
Antisemitism and Jung's concept of the collective unconscious (letter). Bengesser, Mr 414-415
- Juvenile Correctional System**
Note on racial bias in the admission of children and adolescents to state mental health facilities versus correctional facilities in New York. Kaplan, Je 768-772
- K**
- Kleptomania**
Kleptomania and shoplifting (letter). Cupchik, reply of Goldman, Au 1119-1120
On kleptomania (letter). Goldman, Je 848

L

- Lactate** see **Sodium Lactate**
- Late Luteal Phase Dysphoric Disorder**
Course of premenstrual syndrome symptom severity after treatment. Freeman, Ap 531-533
- Late luteal phase dysphoric disorder in 670 women evaluated for premenstrual complaints. Hurt, Ap 525-530
- Nocturnal temperature in LLPDD (letter). Lipman, reply of Severino, Je 850-851
- Lawsuits** see **Forensic Psychiatry**; specific cases
- Learned Helplessness**
Learned helplessness and urinary MHPG levels in unipolar depression. Samson, Je 806-809
- Learning**
Technique for training schizophrenic patients in illness self-management: a controlled trial. Eckman, No 1549-1555
- Lecithin**
Spouses' assessments of Alzheimer patients' response to THA and lecithin (letter). Fitzen, Ap 575
- Legislation** see also **Forensic Psychiatry**; specific cases
Impact of antipsychotic drug regulations on psychotropic prescribing practices in nursing homes. Rovner, Oc 1390-1392
- Judicial and legislative responses to cost containment. Sederer, Se 1157-1161
- Lethal Catatonia**
Lyell syndrome and lethal catatonia: a case for ECT (letter). Weller, Au 1114
- Life Events**
Relationship between adolescent suicidal behavior and life events in childhood and adolescence. de Wilde, Ja 45-51
- Transduction of psychosocial stress into the neurobiology of recurrent affective disorder. Post, Au 999-1010
- Light Therapy**
Bright light treatment of behavioral and sleep disturbances in patients with Alzheimer's disease. Satlin, Au 1028-1032
- Retinopathy and bright light therapy (letter). Walker, reply of Vanselow, No 1610-1611
- Does light therapy present an ocular hazard? (letter). Remé, De 1762-1763
- Lithium**
Double-blind comparison of valproate and lithium in the treatment of acute mania. Freeman, Ja 108-111
- Lithium, benzodiazepines, and sexual function in bipolar patients. Ghadirian, Je 801-805
- Lithium-discontinuation-induced refractoriness: preliminary observations. Post, De 1727-1729
- Lithium treatment of a bipolar patient with cystic fibrosis (letter). Turkel, Ap 574
- Treatment of neuroleptic-resistant mania and schizoaffective disorders (letter). de Beaupaire, reply of Garza-Traviño, No 1614-1615
- Verapamil versus lithium in acute mania. Garza-Traviño, Ja 121-122 (letter: de Beaupaire, No 1614)
- LSD**
Potential interaction of LSD and fluoxetine (letter). Picker, Je 843-844

Lying

- "Pseudohypermnesia": a conscious effort to avoid telling the truth (letter). Strauss, Fe 274-275

M

- Magnetic Resonance Imaging**
Evidence of dysfunction of a prefrontal-limbic network in schizophrenia: a magnetic resonance imaging and regional cerebral blood flow study of discordant monozygotic twins. Weinberger, Jy 890-897
- Frontal, temporal, and striatal proton relaxation times in schizophrenic patients and normal comparison subjects. Williamson, Ap 549-551
- High-intensity signals in Alzheimer's disease without cerebrovascular risk factors: a magnetic resonance imaging evaluation. Kumar, Fe 248-250
- Magnetic resonance imaging in the diagnosis of dementia (letter). Dentino, reply of Rabins, Mr 419
- Magnetic resonance imaging of the posterior fossa in autistic adults. Garber, Fe 245-247
- Qualitative assessment of brain morphology in acute and chronic schizophrenia. Lieberman, Je 784-794
- White matter hyperintensity signals in psychiatric and nonpsychiatric subjects. Brown, My 620-625
- Magnetic Resonance Spectroscopy**
Accumulation of fluoxetine and norfluoxetine in human brain during therapeutic administration. Renshaw, No 1592-1594
- Malingering**
Battered woman syndrome (letter). Blumberg, My 714-715
- Mania**
Antidepressant-induced mania in obsessive-compulsive disorder (letter). Vieta, reply of Steiner, Se 1282-1283
- Blunting growth hormone release in mania (letter). Coupland, reply of Dinan, Se 1286-1287
- Clinical and research implications of the diagnosis of dysphoric or mixed mania or hypomania. McElroy, De 1633-1644
- Comorbidity in mania at first hospitalization. Strakowski, Ap 554-556
- Double-blind comparison of valproate and lithium in the treatment of acute mania. Freeman, Ja 108-111
- Mania and AIDS (letters). Holmes, Whitefield, reply of Kiebertz, Ap 583-584
- Mania compared with unipolar depression in old age. Shulman, Mr 341-345
- Mania during hemodialysis: causal or casual association? (letter). Benazzi, Mr 414
- Mania in late life: focus on age at onset. Young, Jy 867-876
- Prediction of outcome in mania by mood-congruent or mood-incongruent psychotic features. Tohen, No 1580-1584
- Prospective study of neuroleptic-induced dystonia in mania and schizophrenia. Khanna, Ap 511-513
- Treatment of neuroleptic-resistant mania and schizoaffective disorders (letter). de Beaupaire, reply of Garza-Traviño, No 1614-1615
- Verapamil versus lithium in acute mania. Garza-Traviño, Ja 121-122 (letter: de Beaupaire, No 1614)

Manic Depression see **Affective Disorders**

MAOIs see **Antidepressants**

MDMA see "Ecstasy"

Media

- Fluoxetine, suicidal ideation, and aggressive behavior (letter). Selzer, My 708-709
- Media coverage versus fluoxetine as the cause of suicidal ideation (letter). Ioannou, Ap 572

Medicaid

- Community mental health and mental retardation services in the United States: a comparative study of resource allocation. Brad-dock, Fe 175-183

Medical Model

- Clinical problem solving and the biopsychosocial model. Sadler, Oc 1315-1323

Medicare

- Measuring the determinants of work values for psychiatrists' services in the resource-based relative value scale study. Dorwart, De 1654-1659

- Psychiatric outpatient practice: patterns and policies. Olfson, No 1492-1498

Meditation

- Effectiveness of a meditation-based stress reduction program in the treatment of anxiety disorders. Kabat-Zinn, Jy 936-943

Mefloquine

- Acute depressive symptoms after mefloquine treatment (letter). Caillon, My 712

Melancholia see **Depression**

"Memoir on Madness"

- Philippe Pinel's "Memoir on Madness" of December 11, 1794: a fundamental text of modern psychiatry. Weiner, Je 725-732

 John Paul Spiegel, MD, 1911–1991 (in memoriam). Pollock, Ja 7–8

Obsessive-Compulsive Disorder

Accumulation of fluoxetine and norfluoxetine in human brain during therapeutic administration. Renshaw, No 1592-1594

Adverse vascular effects associated with fluoxetine (letter). Gunzberger, De 1751

Antidepressant-induced mania in obsessive-compulsive disorder (letter). Vieta, reply of Steiner, Se 1282-1283

Changes in *DSM-III-R* axis II diagnoses following treatment of obsessive-compulsive disorder. Ricciardi, Je 829-831

Development of transient obsessive-compulsive symptoms during treatment with clozapine (letter). Patil, Fe 272

Increasing frequency of the diagnosis of obsessive-compulsive disorder. Stoll, My 638-640

Ineffectiveness of clomipramine for obsessive-compulsive symptoms in a patient with schizophrenia (letter). Bark, Ja 136-137

Obsessive-compulsive disorder in relation to body dysmorphic disorder (letter). Tanquary, reply of Phillips, Se 1283-1284

Oculomotor performance in obsessive-compulsive disorder. Tien, My 641-646

Onset of obsessive-compulsive disorder in pregnancy. Neziroglu, Jy 947-950

Oxytocin and vasopressin in obsessive-compulsive disorder (letter). Salzberg, My 713-714

Response of obsessive-compulsive disorder and trichotillomania to serotonin reuptake blockers (letter). Graae, Ja 149-150

Serotonin and effect sizes of antiobsessive agents (letter). Pato, Mr 420-421

Tics and Tourette's disorder: a 2- to 7-year follow-up of 54 obsessive-compulsive children. Leonard, Se 1244-1251

Onset of Illness

Change in ideational content as a prodromal symptom in affective disorders (letter). Badal, reply of Fava, Mr 427-428

Mania in late life: focus on age at onset. Young, Jy 867-876

No gender effect on age at onset in familial schizophrenia? (letter). Leboyer, Oc 1409

Onset of obsessive-compulsive disorder in pregnancy. Neziroglu, Jy 947-950

Onset of panic disorder. Faravelli, Je 827-828

Opiates

Use of cocaine to prevent opiate withdrawal (letter). Rosen, No 1609

Opioid

Opioid system and the placebo response (letter). Lichtigfeld, Fe 276 (letter: Lavin, De 1760)

Outcome

Alprazolam plasma concentrations and treatment response in panic disorder and agoraphobia. Lesser, No 1556-1562

Anxiety syndromes as epiphenomena of primary major depression: outcome and familial psychopathology. Coryell, Ja 100-107

Brief treatment of emergency room patients with panic attacks. Swinson, Jy 944-946

Can mildly depressed outpatients with atypical depression benefit from antidepressants? Stewart, My 615-619

Combined pharmacotherapy and psychotherapy in the acute and continuation treatment of elderly patients with recurrent

major depression: a preliminary report. Reynolds, De 1687-1692

Conservatorship for gravely disabled psychiatric patients: a four-year follow-up study. Lamb, Jy 909-913

Course of premenstrual syndrome symptom severity after treatment. Freeman, Ap 531-533

Crossover study of focused cognitive therapy for panic disorder. Beck, Je 778-783

Deterioration in premorbid functioning in schizophrenia: a developmental model of negative symptoms in drug-free patients. Kelley, No 1543-1548

Differential response of seven subjects with autistic disorder to clomipramine and desipramine. Gordon, Mr 363-366

Duration of psychosis and outcome in first-episode schizophrenia. Loebel, Se 1183-1188

Effectiveness of a meditation-based stress reduction program in the treatment of anxiety disorders. Kabat-Zinn, Jy 936-943

Efficacy of brief dynamic psychotherapy: a meta-analysis. Crits-Christoph, Fe 151-158

Haloperidol plasma levels and clinical response: a therapeutic window relationship. Van Putten, Ap 500-505

Hypothalamic-pituitary-adrenal axis hyperactivity and psychosis: recovery during an 8-year follow-up. Coryell, Au 1033-1039

Involuntary interventions: does the benefit exceed the cost? (letter). Schwartz, replies of Berlin, Cournos, Mr 424-426

Melancholic/endogenous depression and response to somatic treatment and placebo. Peselow, Oc 1324-1334

Mental health status and community adjustment after treatment in a residential treatment program for homeless veterans. Leda, Se 1219-1224

Opioid system and the placebo response (letter). Lichtigfeld, Fe 276 (letter: Lavin, De 1760)

Outcome of schizophrenia (letter). Kopolowicz, reply of Marengo, Mr 426-427

Outcome study of psychotherapy for patients with borderline personality disorder. Stevenson, Mr 358-362

Prediction of outcome in mania by mood-congruent or mood-incongruent psychotic features. Tohen, No 1580-1584

Recovery and major depression: factors associated with twelve-month outcome. Keitner, Ja 93-99 (letter: Bennett, Au 1127-1128)

Recovery and relapse from major depressive disorder in the elderly. Hinrichsen, No 1575-1579

Treatment of tardive dyskinesia with vitamin E. Egan, Je 773-777

Outpatients

AIDS/HIV risk behavior among the chronically mentally ill. Kelly, Jy 886-889

AIDS policy: guidelines for outpatient psychiatric services (off acts). American Psychiatric Association Commission on AIDS, My 721

Psychiatric outpatient practice: patterns and policies. Olsson, No 1492-1498

Oxytocin

Oxytocin and vasopressin in obsessive-compulsive disorder (letter). Salzberg, My 713-714

P

Pain

Dissociation in women with chronic pelvic pain. Walker, Ap 534-537

Painful sensory symptoms in neuroleptic-induced extrapyramidal syndromes. Decina, Au 1075-1080

Pancreatitis

Acute pancreatitis associated with clozapine use (letter). Martin, My 714

Panic

Adrenergic receptor genes as candidate genes for panic disorder: a linkage study. Wang, Ap 470-474

Alprazolam plasma concentrations and treatment response in panic disorder and agoraphobia. Lesser, No 1556-1562

Amelioration of mitral valve prolapse after treatment for panic disorder. Coplan, No 1587-1588

Antidepressants, panic disorder, and PTSD (letter). Pohl, De 1752-1753

Are panic attacks traumatic stressors? McNally, Je 824-826

Blood groups in panic disorder (letter). Emmanuel, Mr 410

Crossover study of focused cognitive therapy for panic disorder. Beck, Je 778-783

CSF cholecystokinin concentrations in patients with panic disorder and in normal comparison subjects. Lydiard, My 691-693

Effectiveness of a meditation-based stress reduction program in the treatment of anxiety disorders. Kabat-Zinn, Jy 936-943

Effects of sodium lactate infusion on cisternal lactate and carbon dioxide levels in nonhuman primates. Coplan, Oc 1369-1373

High cholesterol levels in patients with panic disorder. Bajwa, Mr 376-378

Hyperventilation-induced cerebral ischemia in panic disorder and effect of nimodipine. Gibbs, No 1589-1591

Hysterectomy in patients with panic disorder (letter). Swales, Je 846-847

International reliability of a diagnostic intake procedure for panic disorder. Williams, Ap 560-562

Latent structure of anxiety symptoms in anxiety disorders. Kenardy, Au 1058-1061

Onset of panic disorder. Faravelli, Je 827-828

Panic disorder history in the families of patients with angiographically normal coronary arteries. Kushner, No 1563-1567

Panic disorder in Benin, West Africa (letter). Bertschy, Oc 1410

Panic disorder in children and adolescents: a review. Moreau, Oc 1306-1314

Protective effects of imipramine maintenance treatment in panic disorder with agoraphobia. Mavissakalian, Au 1053-1057

Pubertal stage and panic attack history in sixth- and seventh-grade girls. Hayward, Se 1239-1243

Replication of action of cholecystokinin tetrapeptide in panic disorder: clinical and behavioral findings. Bradwejn, Jy 962-964

Suicidal ideation and suicide attempts among patients with panic disorder: a survey of two outpatient clinics. Friedman, My 680-685

- Paranoia**
Differentiating paranoia and legitimate fears (letter). Menuck, Ja 140-141
Folie à deux involving a dog (letter). Howard, Mr 4142
- Parents**
Borderline patients' perceptions of their parents (letter). Cowdry, reply of Paris, Mr 427 (correction: My 720)
Comorbidity of parental anxiety disorders as risk for childhood-onset anxiety in inhibited children. Rosenbaum, Ap 475-481
From nurture to network: examining links between perceptions of parenting received in childhood and social bonds in adulthood. Parker, Jy 877-885
Initial findings on preventive intervention for families with parental affective disorders. Beardslee, Oc 1335-1340
- Parkinson's Disease**
Anxiety disorders and Parkinson's disease (letter). Iruela, reply of Stein, My 719-720
Cognitive impairment after ECT in patients with parkinson's disease and psychiatric illness (letter). Oh, Fe 271 (letters: Zervas, Rudorfer, Figiel, De 1758-1759)
Depression and Parkinson's disease: a review. Cummings, Ap 443-454
Phenelzine treatment of depression in Parkinson's disease (letter). Hargrave, De 1751-1752
- Patient Care**
Response to the presidential address: patient care for the twenty-first century. English, Se 1142-1144
- Patients**
Ethics complaints against female psychiatrists. Mogu, My 651-653
Patient's opinions concerning side effects of depot neuroleptics (letter). Buis, Je 844-845
- Persian Gulf War see Combat; Posttraumatic Stress Disorder**
- Personality Disorders see also specific diagnoses**
Antisocial behavior of intravenous drug abusers: implications for diagnosis of antisocial personality disorder. Brooner, Ap 482-487
Changes in *DSM-III-R* axis II diagnoses following treatment of obsessive-compulsive disorder. Ricciardi, Je 829-831
Childhood factors in adult self-destructive behavior (letter). Paris, reply of van der Kolk, Se 1280-1281
Cognitive impairment in dramatic personality disorders (letter). Burgess, Ja 136
Comorbidity of personality disorders (letter). O'Boyle, reply of Oldham, No 1611
Diagnosis of *DSM-III-R* personality disorders by two structured interviews: patterns of comorbidity. Oldham, Fe 213-220 (letter: O'Boyle, No 1611)
Ethnological approach to self-injurious behavior (letter). Novello, reply of Winchel, De 1763-1764
Patients' appearance and psychopathology (letter). Lavin, De 1764
Problems and considerations in the valid assessment of personality disorders. Perry, De 1645-1653
Relationship between personality and *DSM-III* axis I disorders in the population: results from an epidemiological survey. Nestadt, Se 1228-1233
- Self-mutilation in personality disorders: psychological and biological correlates. Simeon, Fe 221-226
Unusual presentation of multiple sclerosis (letter). Averbuch-Heller, Mr 410-411
PET see Positron Emission Tomography
- Pharmacotherapy**
Gender differences in pharmacokinetics and pharmacodynamics of psychotropic medication. Yonkers, My 587-595
Pharmacologic and cognitive-behavioral treatment for bulimia nervosa: a controlled comparison. Agras, Ja 82-87
Pharmacotherapy and psychotherapy for major depression in a man with AIDS (letter). Sullivan, Ja 138
Prescription writing (letter). Nelson, reply of Hartmann, Mr 430-431
- Phencyclidine**
Phencyclidine and schizophrenia (letter). Kornhuber, reply of Zukin, Je 848-849
- Phenelzine**
Phenelzine treatment of depression in Parkinson's disease (letter). Hargrave, De 1751-1752
- Philosophy**
Information theory perspective on the mind-body problem (letter). Heritch, reply of Goodman, Mr 428-429
Mind-body problem (letter). Rifkin, reply of Goodman, Je 847-848
Mind-body problem (letters). Jacobs, Knobloch, Setterberg, reply of Goodman, Fe 279-282
On organic unity theory (letter). Greenberg, reply of Goodman, My 716-717
Search: body, mind, and human purpose. Freedman, Jy 858-866
- Physical Anomalies**
Congenital malformations and structural developmental anomalies in groups at high risk for psychosis. McNeil, Ja 57-61
Sylvian fissure size in schizophrenia measured with the magnetic resonance imaging rating protocol of the Consortium to Establish a Registry for Alzheimer's Disease. Schwartz, Se 1195-1198
- Physical Illness and Impairment see also specific disorders; Somatization**
Religious coping and depression among elderly, hospitalized medically ill men. Koenig, De 1693-1700
- Physicians**
Prescription writing (letter). Nelson, reply of Hartmann, Mr 430-431
Resident physician substance use, by specialty. Hughes, Oc 1348-1354
- Pimozide**
Use of pimozide in the Pisa syndrome (letter). Suzuki, Au 1114
- Pinel, Philippe**
Philippe Pinel's "Memoir on Madness" of December 11, 1794: a fundamental text of modern psychiatry. Weiner, Je 725-732
- Pisa Syndrome**
Use of pimozide in the Pisa syndrome (letter). Suzuki, Au 1114
- Placebo**
Opioid system and the placebo response (letter). Lichtigfeld, Fe 276 (letter: Lavin, De 1760)
- Polydipsia**
Correction rate of severe hyponatremia and central pontine myelinolysis (letter). Muller, My 715-716
- Polyserositis**
Polyserositis associated with clozapine treatment (letter). Daly, Se 1274-1275
- Positron Emission Tomography**
Regional cerebral glucose metabolism in bulimia nervosa. Andreason, No 1506-1513
Toward a brain map of auditory hallucinations. Cleghorn, Au 1062-1069
- Posttraumatic Stress Disorder**
Antidepressants, panic disorder, and PTSD (letter). Pohl, De 1752-1753
Are panic attacks traumatic stressors? McNally, Je 824-826
Brief treatment of emergency room patients with panic attacks. Swinson, Jy 944-946
Exposure to atrocities and severity of chronic posttraumatic stress disorder in Vietnam combat veterans. Yehuda, Mr 333-336
Fluoxetine and fluvoxamine in PTSD (letter). March, Mr 413
Phenomenology and course of psychiatric disorders associated with combat-related posttraumatic stress disorder. Mellman, No 1568-1574
Posttraumatic adaptation and distress among adult burn survivors. Roca, Se 1234-1238
Posttraumatic stress disorder among substance users from the general population. Cottler, My 664-670
Posttraumatic stress disorder in an urban population of young adults: risk factors for chronicity. Breslau, My 671-675
Predictors of posttraumatic stress disorder after burn injury. Perry, Jy 931-935
PTSD and risk of suicide (letter). Pollock, reply of Hendin, Ja 142-143
Symptoms of PTSD in 124 survivors of the Holocaust. Kuch, Mr 337-340
- Prediction**
Duration of psychosis and outcome in first-episode schizophrenia. Loebel, Se 1183-1188
Prediction of outcome in mania by mood-congruent or mood-incongruent psychotic features. Tohen, No 1580-1584
Predictors of posttraumatic stress disorder after burn injury. Perry, Jy 931-935
- Pregnancy**
Onset of obsessive-compulsive disorder in pregnancy. Neziroglu, Jy 947-950
Psychoanalytic conceptualization of perinatal loss: a multidimensional model. Leon, No 1464-1472
- Premenstrual Syndrome see also Late Luteal Phase Dysphoric Disorder**
Course of premenstrual syndrome symptom severity after treatment. Freeman, Ap 531-533
Does light therapy present an ocular hazard? (letter). Remé, De 1762-1763
Late luteal phase dysphoric disorder in 670 women evaluated for premenstrual complaints. Hurt, Ap 525-530
Nocturnal temperature in LLPDD (letter). Lipman, reply of Severino, Je 850-851
- Premorbid Function**
Deterioration in premorbid functioning in schizophrenia: a developmental model of negative symptoms in drug-free patients. Kelley, No 1543-1548
- Prescribing Practices**
Impact of antipsychotic drug regulations on

- psychotropic prescribing practices in nursing homes. Rovner, Oc 1390-1392
- Priapism**
Clozapine-induced priapism (letter). Ziegler, Fe 272-273 (correction: Au 1129)
- Prison Psychiatry**
Debate on treating individuals incompetent for execution. Heilbrun, My 596-605
- Prolactin**
Elevated cortisol concentrations and the diminished prolactin response to fenfluramine (letter). Mitchell, reply of Dinan, Je 851-852
Serum prolactin levels in homosexual and bisexual men with HIV infection. Gorman, Mr 367-370
- Propranolol**
Randomized, double-blind, crossover, placebo-controlled comparison of propranolol and betaxolol in the treatment of neuroleptic-induced akathisia. Dumon, My 647-650
- Psychiatrists**
Ethics complaints against female psychiatrists. Mogu, My 651-653
National study of psychiatrists' professional activities. Dorwart, No 1499-1505
Protecting patients from clinician-patient sexual contact (letter). Bursztajn, Se 1276
Psychiatric outpatient practice: patterns and policies. Olsson, No 1492-1498
Psychotherapist-patient sexual contact after termination of treatment (letter). Brown, Aronson, Schoener, Ritchie, Friedman, Burnham, Hersen, Drummond, Pearlman, Sonnenberg, Sapir, Spindler, Anderson, Hamburg, Murphy, Pincus, Kotin, Auster, Shevitz, Fassler, reply of Appelbaum, Jy 979-989
Sex with former patients almost always unethical (editorial). Lazarus, Jy 855-857
When a patient commits suicide (letters). Schacht, Pearlman, reply of Kaye, Fe 282-283
- Psychiatry**
Alcohol and addictions (letters). Levy, Hughes, Adinoff, reply of Khantzian, Au 1117-1119
Anne Sexton's biography (letter). Wilmer, No 1621-1622
Challenge for psychiatry (letter). Pinheiro, Ap 584-585
Defining the future in medical education (editorial). Pardes, Oc 1293-1294
Environmental factors in psychiatric disorders (letter). Pardes, Mr 423
Information theory perspective on the mind-body problem (letter). Heritch, reply of Goodman, Mr 428-429
Measuring the determinants of work values for psychiatrists' services in the resource-based relative value scale study. Dorwart, De 1654-1659
Mind-body problem (letters). Jacobs, Knobloch, Setterberg, reply of Goodman, Fe 279-282; Rifkin, reply of Goodman, Je 847-848
National study of psychiatrists' professional activities. Dorwart, No 1499-1505
Need for integrating environmental and biological factors in psychiatry (letter). Strauss, Ja 147
On organic unity theory (letter). Greenberg, reply of Goodman, My 716-717
Philippe Pinel's "Memoir on Madness" of December 11, 1794: a fundamental text of modern psychiatry. Weiner, Je 725-732
- Prescription writing (letter). Nelson, reply of Hartmann, Mr 430-431
Presidential address: reflections on humane values and biopsychosocial integration. Hartmann, Se 1135-1141
Psychiatric outpatient practice: patterns and policies. Olsson, No 1492-1498
Psychiatry and the homeless mentally ill: a reply to Dr. Lamb. Mossman, Jy 951-957
Psychosocial rehabilitation and psychiatry in the care of long-term patients. Bachrach, No 1455-1463
Response to the presidential address: patient care for the twenty-first century. English, Se 1142-1144
Search: body, mind, and human purpose. Freedman, Jy 858-866
Sociocultural perspectives on substance abuse disorders (letter). Walsh, reply of Westermeyer, De 1760-1761
Psychiatry Resident In-Training Examination (PRITE)
Training directors' opinions about the Psychiatry Resident In-Training Examination (PRITE). Webb, Ap 521-524
- Psychobiology**
Psychodynamic psychiatry in the "decade of the brain." Gabbard, Au 991-998
- Psychodynamic Therapy**
Efficacy of brief dynamic psychotherapy: a meta-analysis. Crits-Christoph, Fe 151-158
Psychodynamic psychiatry in the "decade of the brain." Gabbard, Au 991-998
- Psychodynamics**
Dissociation and suicide in the young (letter). Jensen, reply of Hendin, Ap 578-579
Suicidality and the young (letter). White, reply of Hendin, Je 849-850
Psychological Tests see **Tests, Psychological**
Psychopathology see also **specific diagnoses**
Automobile driving by psychiatric patients (letter). Hollister, Fe 274 (letter: Iulian, No 1615)
Conditions not attributable to a mental disorder (letter). Mazzoli, reply of de Figueiredo, Mr 423
Credibility of patients in psychiatric research (letter). Powell, reply of Sanders, Au 1126-1127
Effectiveness and replicability of modules for teaching social and instrumental skills to the severely mentally ill. Wallace, My 654-658
Elderly Israeli Holocaust survivors during the Persian Gulf War: a study of psychological distress. Solomon, De 1707-1710
Ethnological approach to self-injurious behavior (letter). Novello, reply of Winchel, De 1763-1764
Fluoxetine and suicidal preoccupation (letter). Ashleigh, De 1750
G proteins: implications for psychiatry. Manji, Je 746-760
Homeless mentally ill or mentally ill homeless? Cohen, Je 816-823
Long-term effects of incest (letter). Kinzl, reply of Brown, Ap 578
Obesity and multiple personality disorder (letters). Wetsman, Chandarana, reply of Black, No 1612-1613
Predicting substance use in late adolescence: results from the Ontario Child Health Study follow-up. Boyle, Je 761-767
- Prevalence of mental disorder in 88 morbidly obese bariatric clinic patients. Black, Fe 227-234
Psychiatric correlates of incest in childhood. Pribor, Ja 52-56 (letter: Karagianis, Se 1278)
Psychopathology, hypnotizability, and dissociation. Frischholz, No 1521-1525
Regarding the use and accuracy of the family history method (letter). Horwath, reply of Kendler, Au 1122-1123
Sequelae of denied abortion (letter). Storch, Fe 275
White matter hyperintensity signals in psychiatric and nonpsychiatric subjects. Brown, My 620-625
- Psychosis** see also **specific diagnoses**
Alexithymia and the ECA study (letter). Lesser, reply of Simon, Se 1281-1282
Congenital malformations and structural developmental anomalies in groups at high risk for psychosis. McNeil, Ja 57-61
Duration of psychosis and outcome in first-episode schizophrenia. Loebel, Se 1183-1188
Hypothalamic-pituitary-adrenal axis hyperactivity and psychosis: recovery during an 8-year follow-up. Coryell, Au 1033-1039
Prediction of outcome in mania by mood-congruent or mood-incongruent psychotic features. Tohen, No 1580-1584
Prevalence of substance abuse or dependence diagnoses on an inpatient inner city psychiatric unit (letter). Storch, reply of Gogek, Se 1285-1286
Psychotic (delusional) major depression: should it be included as a distinct syndrome in DSM-IV? Schatzberg, Je 733-745
Psychotic symptoms and suicidal behavior in hospitalized children. Livingston, No 1585-1586
Reliability of best-estimate diagnosis in genetic linkage studies of major psychoses: results from the Quebec pedigree studies. Maziade, De 1674-1686
Schizoaffective disorder and affective disorders with mood-incongruent psychotic features: keep separate or combine? evidence from a family study. Maier, De 1666-1673
Utilization of neuropsychiatric diagnostic tests for general hospital patients with mental disorders. Olsson, De 1711-1717
- Psychosocial Adjustment**
Psychosocial rehabilitation and psychiatry in the care of long-term patients. Bachrach, No 1455-1463
- Psychotherapy**
Combined pharmacotherapy and psychotherapy in the acute and continuation treatment of elderly patients with recurrent major depression: a preliminary report. Reynolds, De 1687-1692
Cost-effectiveness of psychotherapy: a plan for research. Krupnick, Oc 1295-1305
Dynamic cognitive therapy anyone? (letter). Larson, Jy 990
Efficacy of brief dynamic psychotherapy: a meta-analysis. Crits-Christoph, Fe 151-158
Factors affecting patient dropout rates (letter). Good, reply of Sledge, Fe 275-276
Listening healer in the history of psychological healing. Jackson, De 1623-1632
Outcome study of psychotherapy for patients

- with borderline personality disorder. Stevenson, Mr 358-362
- Pharmacotherapy and psychotherapy for major depression in a man with AIDS (letter). Sullivan, Ja 138
- Psychotherapy with Mexican-American patients. Sanchez, My 626-630

HALDOL® Decanoate 50 (haloperidol) HALDOL® Decanoate 100 (haloperidol) For IM Injection Only

Brief Summary

The following is a brief summary only. Before prescribing, see complete prescribing information in HALDOL and HALDOL Decanoate product labeling.

CONTRAINDICATIONS: Since the pharmacologic and clinical actions of HALDOL Decanoate 50 and HALDOL Decanoate 100 are attributed to HALDOL haloperidol as the active medication, CONTRAINDICATIONS, WARNINGS, and additional information are those of HALDOL, modified to reflect the prolonged action. HALDOL is contraindicated in severe toxic central nervous system depression or comatose states from any cause and in individuals who are hypersensitive to this drug or have Parkinson's disease.

WARNINGS: Tardive Dyskinesia: Tardive dyskinesia, a syndrome consisting of potentially irreversible, involuntary, dyskinetic movements may develop in patients treated with antipsychotic drugs. Although the prevalence of the syndrome appears to be highest among the elderly, especially elderly women, it is impossible to rely upon prevalence estimates to predict, at the inception of antipsychotic treatment, which patients are likely to develop the syndrome. Whether antipsychotic drug products differ in their potential to cause tardive dyskinesia is unknown. Both the risk of developing tardive dyskinesia and the likelihood that it will become irreversible are believed to increase as the duration of treatment and the total cumulative dose of antipsychotic drugs administered to the patient increase. However, the syndrome can develop, although much less commonly, after relatively brief treatment periods at low doses. There is no known treatment for established cases of tardive dyskinesia, although the syndrome may remit, partially or completely, if antipsychotic treatment is withdrawn. Antipsychotic treatment, itself, however, may suppress (or partially suppress) the signs and symptoms of the syndrome and thereby may possibly mask the underlying process. The effect that symptomatic suppression has upon the long-term course of the syndrome is unknown. Given these considerations, antipsychotic drugs should be prescribed in a manner that is most likely to minimize the occurrence of tardive dyskinesia. Chronic antipsychotic treatment should generally be reserved for patients who suffer from a chronic illness that 1) is known to respond to antipsychotic drugs, and 2) for whom alternative, equally effective, but potentially less harmful treatments are not available or appropriate. In patients who do require chronic treatment, the smallest dose and the shortest duration of treatment producing a satisfactory clinical response should be sought. The need for continued treatment should be reassessed periodically. If signs and symptoms of tardive dyskinesia appear in a patient on antipsychotics, drug discontinuation should be considered. However, some patients may require treatment despite the presence of the syndrome. (For further information about the description of tardive dyskinesia and its clinical detection, please refer to ADVERSE REACTIONS.)

Neuroleptic Malignant Syndrome (NMS): A potentially fatal symptom complex sometimes referred to as Neuroleptic Malignant Syndrome (NMS) has been reported in association with antipsychotic drugs. Clinical manifestations of NMS are hyperpyrexia, muscle rigidity, altered mental status (including catatonic signs) and evidence of autonomic instability (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac dysrhythmias). Additional signs may include elevated creatine phosphokinase, myoglobinuria (rhabdomyolysis) and acute renal failure. The diagnostic evaluation of patients with this syndrome is complicated. In arriving at a diagnosis, it is important to identify cases where the clinical presentation includes both serious medical illness (e.g., pneumonia, systemic infection, etc.) and untreated or inadequately treated extrapyramidal signs and symptoms (EPS). Other important considerations in the differential diagnosis include central anticholinergic toxicity, heat stroke, drug fever and primary central nervous system (CNS) pathology. The management of NMS should include 1) immediate discontinuation of antipsychotic drugs and other drugs not essential to concurrent therapy; 2) intensive symptomatic treatment and medical monitoring; and 3) treatment of any concomitant serious medical problems for which specific treatments are available. There is no general agreement about specific pharmacological treatment regimens for uncomplicated NMS. If a patient requires antipsychotic drug treatment after recovery from NMS, the potential reintroduction of drug therapy should be carefully considered. The patient should be carefully monitored, since recurrences of NMS have been reported. Hyperpyrexia and heat stroke, not associated with the above symptom complex, have also been reported with HALDOL.

Usage in Pregnancy: (see PRECAUTIONS - Usage in Pregnancy)

Combined Use With Lithium: (see PRECAUTIONS-Drug Interactions)

General: Bronchopneumonia, sometimes fatal, has followed use of antipsychotic drugs, including haloperidol. Prompt remedial therapy should be instituted if dehydration, hemoconcentration or reduced pulmonary ventilation occur, especially in the elderly. Decreased serum cholesterol and/or cutaneous and ocular changes have been reported with chemically-related drugs, although not with haloperidol. See PRECAUTIONS - Information for Patients for information on mental and/or physical abilities and on concomitant use with other substances.

PRECAUTIONS: Administer cautiously to patients: (1) with severe cardiovascular disorders, due to the possibility of transient hypotension and/or precipitation of anginal pain (if a vasopressor is required, epinephrine should not be used since HALDOL may block its vasopressor activity and paradoxical further lowering of blood pressure may occur; metaraminol, phenylephrine or norepinephrine should be used); (2) receiving anticonvulsant medications, with a history of seizures, or with EEG abnormalities, because HALDOL may lower the convulsive threshold. If indicated, adequate anticonvulsant therapy should be concomitantly maintained; (3) with known allergies or a history of allergic reactions to drugs; (4) receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione). Concomitant antiparkinson medication, if required, may have to be continued after HALDOL is discontinued because of different excretion rates; if both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson drugs, are administered concomitantly with HALDOL. When HALDOL is used for mania in bipolar disorders, there may be a rapid mood swing to depression. Severe neurotoxicity may occur in patients with thyrotoxicosis receiving antipsychotic medication, including HALDOL.

The 1, 5, 10 mg HALDOL tablets contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, especially in those who have aspirin hypersensitivity.

Information for Patients: Mental and/or physical abilities required for hazardous tasks or driving may be impaired. Alcohol should be avoided due to possible additive effects and hypotension.

Drug Interactions: Patients receiving lithium plus haloperidol should be monitored closely for early evidence of neurological toxicity and treatment discontinued promptly if such signs appear. As with other antipsychotic agents, it should be noted that HALDOL may be capable of potentiating CNS depressants such as anesthetics, opiates, and alcohol.

Carcinogenesis, Mutagenesis and Impairment of Fertility: No mutagenic potential of haloperidol was found in the Ames Salmonella microsome activation assay. Negative or inconsistent positive findings have been obtained in *in vitro* and *in vivo* studies of effects of haloperidol on chromosome structure and number. The available cytogenetic evidence is considered too inconsistent to be conclusive at this time. Carcinogenicity studies using oral haloperidol were conducted in Wistar rats (dosed at up to 5 mg/kg daily for 24 months) and in Albino Swiss mice (dosed at up to 5 mg/kg daily

for 18 months). In the rat study survival was less than optimal in all dose groups, reducing the number of rats at risk for developing tumors. However, although a relatively greater number of rats survived to the end of the study in high dose male and female groups, these animals did not have a greater incidence of tumors than control animals. Therefore, although not optimal, this study does suggest the absence of a haloperidol related increase in the incidence of neoplasia in rats at doses up to 20 times the usual daily human dose for chronic or resistant patients. In female mice at 5 and 20 times the highest initial daily dose for chronic or resistant patients, there was a statistically significant increase in mammary gland neoplasia and total tumor incidence; at 20 times the same daily dose there was a statistically significant increase in pituitary gland neoplasia. In male mice, no statistically significant differences in incidences of total tumors or specific tumor types were noted. Antipsychotic drugs elevate prolactin levels; the elevation persists during chronic administration. Tissue culture experiments indicate that approximately one-third of human breast cancers are prolactin dependent *in vitro*, a factor of potential importance if the prescription of these drugs is contemplated in a patient with a previously detected breast cancer. Although disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been reported, the clinical significance of elevated serum prolactin levels is unknown for most patients. An increase in mammary neoplasms has been found in rodents after chronic administration of antipsychotic drugs. Neither clinical studies nor epidemiologic studies conducted to date, however, have shown an association between chronic administration of these drugs and mammary tumorigenesis; the available evidence is considered too limited to be conclusive at this time.

Usage in Pregnancy: Pregnancy Category C. Safe use in pregnancy or in women likely to become pregnant has not been established; use only if benefit clearly justifies potential hazards to the fetus.

Nursing Mothers: Infants should not be nursed during drug treatment.

Pediatric Use: Controlled trials to establish the safety and effectiveness of intramuscular administration in children have not been conducted.

ADVERSE REACTIONS: Adverse reactions following the administration of HALDOL Decanoate 50 or HALDOL Decanoate 100 are those of HALDOL haloperidol. Since vast experience has accumulated with HALDOL, the adverse reactions are reported for that compound as well as for haloperidol decanoate. As with all injectable medications, local tissue reactions have been reported with haloperidol decanoate.

CNS Effects: Extrapyramidal Symptoms (EPS) — EPS during the administration of HALDOL (haloperidol) have been reported frequently, often during the first few days of treatment. EPS can be categorized generally as Parkinson-like symptoms, akathisia, or dystonia (including opisthotonos and oculogyric crisis). While all can occur at relatively low doses, they occur more frequently and with greater severity at higher doses. The symptoms may be controlled with dose reductions or administration of antiparkinson drugs such as benztropine mesylate USP or trihexyphenidyl hydrochloride USP. It should be noted that persistent EPS have been reported; the drug may have to be discontinued in such cases. **Withdrawal Emergent Neurological Signs** — Abrupt discontinuation of short-term antipsychotic therapy is generally uneventful. However, some patients on maintenance treatment experience transient dyskinetic signs after abrupt withdrawal. In certain cases these are indistinguishable from "Tardive Dyskinesia" except for duration. It is unknown whether gradual withdrawal will reduce the occurrence of these signs, but until further evidence is available HALDOL should be gradually withdrawn. **Tardive Dyskinesia** — As with all antipsychotic agents HALDOL has been associated with persistent dyskinesias. Tardive dyskinesia, a syndrome consisting of potentially irreversible, involuntary, dyskinetic movements, may appear in some patients on long-term therapy or may occur after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. The syndrome is characterized by rhythmic involuntary movements of tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities and the trunk. There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, this syndrome may be masked. It has been reported that fine vermicular movement of the tongue may be an early sign of tardive dyskinesia and if the medication is stopped at that time the full syndrome may not develop. **Tardive Dystonia** — Tardive dystonia, not associated with the above syndrome, has also been reported. Tardive dystonia is characterized by delayed onset of choreic or dystonic movements, is often persistent, and has the potential of becoming irreversible. **Other CNS Effects** — Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations, and catatonic-like behavioral states which may be responsive to drug withdrawal and/or treatment with anticholinergic drugs.

Body as a Whole: Neuroleptic malignant syndrome (NMS), hyperpyrexia and heat stroke have been reported with HALDOL. (See WARNINGS for further information concerning NMS.)

Cardiovascular Effects: Tachycardia, hypotension, hypertension and ECG changes, including prolongation of the Q-T interval and ECG pattern changes compatible with the polymorphous configuration of torsades de pointes.

Hematologic Effects: Reports of mild, usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis; agranulocytosis rarely reported and only in association with other medication.

Liver Effects: Impaired liver function and/or jaundice.

Dermatologic Reactions: Maculopapular and acneiform reactions, isolated cases of photosensitivity, loss of hair.

Endocrine Disorders: Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia, hypoglycemia and hyponatremia.

Gastrointestinal Effects: Anorexia, constipation, diarrhea, hyper-salivation, dyspepsia, nausea and vomiting.

Autonomic Reactions: Dry mouth, blurred vision, urinary retention, diaphoresis, and priapism.

Respiratory Effects: Laryngospasm, bronchospasm and increased depth of respiration.

Special Senses: Cataracts, retinopathy and visual disturbances.

Other: Cases of sudden and unexpected death have been reported in association with the administration of HALDOL. The nature of the evidence makes it impossible to determine definitively what role, if any, HALDOL played in the outcome of the reported cases. The possibility that HALDOL caused death cannot, of course, be excluded, but it is to be kept in mind that sudden and unexpected death may occur in psychotic patients when they go untreated or when they are treated with other antipsychotic drugs.

Postmarketing Events: Hyperammonemia has been reported in a 5½ year old child with citrullinemia, an inherited disorder of ammonia excretion, following treatment with HALDOL.

IMPORTANT: Full directions for use should be read before HALDOL or HALDOL Decanoate products are administered or prescribed.

For Information on symptoms and treatment of overdose, see full prescribing information.

The short-acting HALDOL injectable form is intended only for acutely agitated psychotic patients with moderately severe to very severe symptoms.

12/30/91

SPRING HOUSE, PA 19477-0776

During dose adjustment or episodes of exacerbation of psychotic symptoms, therapy with HALDOL Decanoate 100 or HALDOL Decanoate 50 can be supplemented with short-acting forms of HALDOL[®] (haloperidol). The side effects of the decanoate products are those of HALDOL. The prolonged action of HALDOL Decanoate 100 and HALDOL Decanoate 50 should be considered in the management of side effects.
